Supplement to the ENGLISH MECHANIC, September 22, 1882.]

ENGLISH MECHANIC

AND

WORLD OF SCIENCE.

WITH WHICH ARE INCORPORATED

"THE MECHANIC," "SCIENTIFIC OPINION," AND "THE BRITISH & FOREIGN MECHANIC."

ILLUSTRATED WITH NUMEROUS PRACTICAL ENGRAVINGS.

VOLUME XXXV.

LONDON:
Office: 31, TAVISTOCK STREET, COVENT GARDEN, W.C.

Sold by all Booksellers and Newsagents in the Kingdom.

1882.

HARVARD

[*Supplement to the ENGLISH MECHANIC, September* 22, 1882.]

INDEX TO VOL. XXXV. ENGLISH MECHANIC.

ABBE, theory of microscopical vision, 190
Abbe's apertometer, 429, 551
Abbot-ford class of N.B. engines, weight of, 111
Aberration: and parallax, 281
  of mirrors, 171, 402
  of parabolic speculum, 351, 452
  spherical, 281, 290
Abscess in groin, 430
Academy boards, 358
Accident: Barton, 405
  Portskewet Pier, 357
  Werrington Junction and Ely, 524
Accidents, railway, and waggon couplings, 574
Accounts, Industrial Company's, 530
Accumulators, Faure's, 549, 572
Acetic acid, gravity of, 507, 549
Achromatic: object-glass, theory of, 130, 297, 344, 371, 393, 418, 440, 489, 537
  telescope, a crown-glass, 273, 343, 352, 402, 536
Achromatism: crown-glass, 501, 549, 593
  of optical instruments, irrationality of the spectrum in its relation to the, 46
Acids, impurities in, 54, 65
Acne, 64
Action of eyepiece, 328
Adhesion of flat driving-belts, 123
Adhesive weight of locomotive, 13,
Adjustment of mirrors, 10, 33, 62, 80
Advances in photography, recent, 445, 471, 494, 517, 541, 589
Advertisements, gratis, 81, 107, 155
Agate, artificial forms of silica resembling, 392
Age: of fossils, some possible sources of error in computing, 445
  of Stonehenge, 519
Ague, 601
Air: and steam, 135
  quantity of required for combustion of coal, 329
Air-pumps, mercurial, 442
Ajax, H.M.S., 602
Alarm, electric, 17
Alarum, 215
Albuminoid substances, 373
Alcoholic solutions, precipitating, 54
"Aldebaran," to, 87, 505
Aldebaran, comites to, 53
Ale, ginger, 64
Alkalimetry, 329
Alloy for silvering metals, 494
Alloys: analysis of, 67
  some notes on, 302
Altazimuth and equatorial new combination, 306, 326, 351, 402
Altitude, quadrant of, 282
Alumina, sulphate of, 361
Aluminium, 361, 384, 404, 431, 480, 549
Amateur: dramatic club, 17, 39
  surgical appliances, 498, 527
American: cloth, 180
  organ, 247, 269, 284, 310, 553
  — two-manual, 219, 285
  tricycle skate, 562
Ammonia, new and delicate test for, 146
Ammonium chloride, purifying, 224
Ampère, 480
Analogy between water-hammer action and earthquake phenomena, 146
Analysis of Japanese bronzes, 516
Analysis: of alloys, 67
  of arguzoid, 375
  of paint, 601
  of refined copper, 54
Analysis: of soap, 197
  of soils, 135
  of soot, 198
  of water, 246, 268
Analysts, Somerset House, 160
Anæsthetics, 54
Andromeda, suspected variable stars in, 400
Andromedæ, iota, 150
Andromedes, the July, 498
Anemometer indications, 481
Aniline colours, arsenic in, 329, 384
Animals: hibernation of, 96, 154
  how they became carnivorous, 493
Ankles, weak, 106
Anti-fat dietary, 454
Antipodes, meat transport from the, 322
Ants, getting rid of, 100, 136
Apertometer, Abbe's, 429, 551
Aperture: and power in the microscope, the relation of, 374, 395
  4·56in., 546, 570
Apology, an, 474
Apparatus: dividing, 290
  gymnastic, 505
  spiral, 367
Applications of electricity, 95, 145, 167, 232
Apsides, motion of the moon's, 474
Aquarium: 480
  front, 334
Aquarius, suspected variable stars in, 400
Aquila, suspected variable stars in, 400
Arago's "Popular Astronomy," 53
Arc: electric, experiments with the, 439
  — in vacuo, 301
Archæological, 602
Arctic meteorological observations, 491
Area of segment of circle, 8
Aries, suspected variable stars in, 427
Areas of circles, 171
Argo, suspected variable stars in, 400
Arguzoid, analysis of, 375
Arm, sick child's, 480
Armature, Siemens's, 456
Arsenic: 549, 553
  in aniline colours, 329, 384
  in wallpapers, 386, 528, 549, 577
Artesian well, 449
Artificial: cable, 37
  forms of silica resembling agate, 392
Artists: canvas for, 37
  science for, 429
Asbestos fireproof paint, 588
Assaying, lessons in, 384
Astatic galvanometer, 180
Astronomical: 18, 101, 161, 238, 247, 270
  bibliography, 252
  books, 192
  eyepieces, 259, 281, 305, 328, 337, 351, 506
  notes, 76, 164, 254, 369, 464, 584
  observation, climate for, 9
  sketches, the blue pr[illegible] for, 305
  telescope, 482
Astronomy, Arago's popular, 53
Atlantic steaming, fast, 348
Atlas, star, for amateurs, 236
Atmospheric nitrogen, 431
Atropine and daturine, coloured reaction of, 518
Auctioneers' responsibilities, 241
Auriga, suspected variable stars in, 427
Auroræ, 79, 198
Austral, the, 359
Australian railway prospects, 267, 318
Autographic transfers for printing processes, 166
Automatic: air v. automatic vacuum brakes, 130, 524
Automatic: arrangement for receiving workmen's time checks, 13, 37, 177
  counting apparatus, 381
  musical instruments, 12, 59, 133, 137
Axioms, Euclid's, 529, 600
Axle for tramcars, jointed, 459

BACILLUS of tuberculosis, 378
Back-gear headstock, 138, 160
Background, photo., 182, 200
Backstays, 174
Bacteria, 314, 359, 362, 408, 480
Bagpipes, 182
Baking, 90
Balance: chemical, 88, 111
  spring, reducing with acid, 17
  springs, 111, 181, 270
  wheel cutting tool, 553
Balloon: 266
  experiments in Germany, 303
Balloons: collodion, 292
  covering silk, 247
Balls, turning wooden, 13
Balmer's and Phillip's gas-stoves, 225
Bankruptcy, 575, 595
Bankrupt's discharge, 595
Bar, boring horizontal, 158
Barlow lens, 53, 216
Barney's improvements in telephones, 369
Barometer: a simple, 217
  Dr. Hay's, 239
Barrel, boring out, 359
Barrels, staining gun, 85, 483
Barton accident and the vacuum brake, 405
Basin, making a green sand, 443
Baskets, bleaching old willow, 483
Bath: gas, 289
  hot-air or vapour, 354, 378, 384, 403, 454, 597, 599
  photo., 159
  Turkish for home use, 130, 157, 181, 289
  — "Gereb Admn's," 354, 378, 403, 597
Baths of Wildbad, 552
Batteries: and coils, power of, 529
  Daniell, 202
  electrical accumulators or secondary, 256, 278, 346, 372, 420, 444
  galvanic, 127
  — from elements alone, 145
  improvements in galvanic, 76
  — in secondary, 561
  Leclanché with and without manganese, 332, 352
  new, 81
  primary and secondary, 352
  secondary, 230, 400, 561, 591
  storage, 18
  — advantages of, 292
  voltaic and storage, recent improvements in, 492, 561
Battery: 18, 178, 246, 270
  a Bennett, 308
  Bennett's, 5, 84, 89, 107, 127, 155, 270
  bichromate, improved, 400
  — powerful, 268, 529
  Bunsen, cheap form of, 263, 381, 430
  — compact form of, 193
  — connections, 290, 382, 400, 410, 430, 433
  constant, 497
  current, strength of, 160
  Daniell's, 18
  effect of heat on a, 279
  fitting up, 17
  for electric clock, 457
  for plating, 290
Battery: Fournier's, 394
  Fuller's, 160, 179, 429
  Gaiffe's medical, 359
  gas, improvements of the, 168
  Grenet's, 434
  Higgin's cascade, 165
  Leclanché, cleaning, 456
  — connections of, 263, 269, 284, 290, 335, 382
  polarisation in, measuring, 199
  Sellon-Volckmar secondary, 141
  size of, 338
  small quantity, 178, 179
  storage, 180, 284, 600
  Sutton's secondary, 180, 200, 214, 247, 291
  tinpot, 5, 84, 89, 107, 127
  Tolman's, 107, 155
Bearing, bicycle backwheel, 63
Bearings: lubricating, 188
  roller, adjustable, 330
Beat in violoncello, 15
Beaumont's photographic shutter, 381
Beckett's, Sir E., screwdriver improvement, 63, 85, 107, 130
Bed, concrete, for engine, 271, 291, 313
Bedstead table, portable, 241
Beeswax, bleaching, 54
Beetles, classification of British, 68
Beetroot, wine from, 561
Beginner's method of observing, 593
Bell: electric, 247
  telephone v., 41
Bellows: camera, 224, 287
  for brazing, 387
  leather for, 157, 387
Bells: electric and lightning, 269
  electric, making magnets for, 18, 335
  — connecting, 180
  — faulty, 409
Belts: adhesion of flat driving, 123
  glueing splicings of, 245, 312
Bench, carpenter's, 289
Bending: copper pipes, 434
  wood, 15, 384, 599
Bennett battery, a, 308
Bennett's battery, 84, 89, 107, 155, 270
Berenices, coma (Otto Struve 266), 192
Berliner violin: 309, 332, 385, 404, 427, 453, 481, 501
  improvement, 594
Bevel wheels, 223
Bibliographie générale de l'astronomie, 252
Bichromate battery: and intensity coil, 246
  Higgins's cascade, 175
  — improved, 400
  — powerful, 268, 529
Bicycle: 43
  back wheel bearing, 63
  forks, brazing, 177
  head, self-steering, 346
  hubs, drilling, 554
  making, 90, 112, 135, 158, 178
  Merlin patent, 386
  spokes, tinning, 64
  tires, 554
Bicycles and tricycles, exhibition of, at Birmingham, 73
Biliousness, 478, 481, 505, 528
Bills of sale, 531
Binding screw, substitute for, 182, 200
Bird-cage making, 504, 528
Birmingham: exhibition of bicycles and tricycles, 73
  wire gauge, 14, 110
Birmingham's new variable in Cygnus, 474
Bisulphide prism, 532

Black: Forest, Wildbad and its cures in, 353, 380, 406
  ink, 570
  paint for window-sashes, 407
  shellac varnish, 579, 601, 603
  transfer paper, 483
  vegetable, 16
Blacking, moulder's 201
Blackleading scorched iron, 111
Blake transmitter, 224, 244, 267
Blast furnace, 480
Bleaching: beeswax, 54
  clothes, 224, 244, 358
  cotton, 288, 334
  old willow baskets, 483
  ozonised oxygen for, 188
  straw hats, 313
Blind man's vision, 398, 451, 502
Bloater paste, 507
Block, Smeaton's, 425, 450, 474, 475
Blood, circulation of in tadpole's tail, 216
Blowing: engines, 157
  harmonium, 152
Blue process for astro. sketches, 305
Boards, Academy, 358
Boat: building, 434
  canvas, 506
Bobbin ends, polishing, 531
Boehm system, 361
Bogie carriages, Midland, 135
Boiler: 87, 137, 480
  cleaning, 505
  construction, improvements in, 423
  corrosion, 482
  explosion experiments, Lawson's, 229
  Explosions Act, 463
  kitchen, safety-valve for, 314, 337
  locomotive, 482, 577
  making, 334
  model steamboat, 61, 86, 101, 578, 600
  patched, 137
  plates, punch for, 334
  pump, 90, 112, 178
  riveting copper, 113, 158
  strains, calculating, 458
  tubular for launch, 410, 528
  vertical, 555
Boilers: calculating size and power of, 287, 386, 530
  launch tubular, 410, 528
Bolton range-finder, 298
Bombay university, clock and carillons for, 587
Bone-caves, ossiferous or, 58
Bones, calcination of, 457
Bookbinding: 203
  in vellum, 386
Bookcase, cheap and ornamental, 34, 63, 175
Book-edges, gilding, 431
Boomerang, 577, 599
Boötes, suspected variable stars in, 427
Boötis: 349
  mu^{1}, 150, 192
  xi, 399
Boots, burnishing ink for edges of, 15
Boring horizontal bar, 158
Botanical specimens, 243
Bottle, killing, 601
Bourdon pipes, 156
Bow legs, 106
Bowels, pain in the, 478
Bowls, enamelled, 455
Box, changing, for dry-plates, 240, 285
Brake: couplings, universal, 202
  failures, 557
  for omnicycle, 266
  formula for resistance, &c., 157
  Great Western vacuum, 312, 334, 383
  Gresham's automatic vacuum, 108
  Guérin, 552
  Kitson's steam, 531, 554
  power on goods trains, 531
  trials, 110
  two-minute, 357
  Westinghouse automatic vacuum, 195
Brakes: action of, 554
  automatic air v. automatic vacuum, 130, 524
  bill, continuous, 311
  continuous, 10, 36, 83, 109, 159, 454
  — return, 109, 155, 595
  Holbech's 18
  Mr. Reynolds's book on continuous, 439
  on the Midland, 456
  practical test of the rival, 511
  railway, 130, 177, 195, 334, 383
  tricycle, 526
  universal couplings for, 156
  vacuum, 111
  — steam used by, 177
Brashear, to Mr., 8, 238, 401
Brass: bronzing, 13
  casting, 19
  cleaning and relacquering, 40
  dead black for, 603
  discs, stamping, 481
  door-plates, 291
  dulling, 334
  dust, melting, 292
  mixing, for melting, 315
  re-dipping, 482
  wire, hardening, 41
Brazing: bellows for, 387
  bicycle forks, 177
Bread, 313, 359, 573
Brennan's torpedo, 444
Brick-burning, product of, 505
Brick-kiln with down-draught, 312, 358, 407
Bricks: discolouration of, 18
  magnetic, 411
Bridge: opening, 362
  Wheatstone's, 16, 85
Brightness of stars, 79
Bright's disease, 357
Bristol and Exeter locos., 267
British: association, the president's address, 563
  — addresses, 590
  navy, the, 118
  races, future of the, 568
Broadwell's breechloading system, 552
Brompton and the patent office, 570
Bronzes, analyses of the Japanese, 516
Bronzing: brass, 13
  cardboard, 531, 553
  small castings, 291
Brooches: coin, 290
  silver filagree, cleaning, 435, 457
Brown marks on skin, 195
Browning-With reflector, work done by an 8·5in., 349
Bruises, cuts and, 269, 290
Building, cottage, 383
Bumping noise in engine, 225, 245
Bunsen battery: cheap form of, 263, 381, 430
  compact form of, 193
  connections, 410, 433
  for plating, 270
Burglar alarm platform, 379
Burners, revolving gas, 244
Burnishing, 169

CABBAGE-broccoli, a, 578
Cable, artificial, 37
Calcination of bones, 457
Calcium: chromate of, 42
  sulphide of, 42
Calculating: machine, 528
  — Huxley's, 56, 108, 154
  size and power of boilers, 287, 386, 530
  watch and clock trains, 157
Caledonian engines, 135, 245, 358
Calender rollers, turning, 68, 87
Calorific intensity, 133, 177
Calver reflector, double-star work performed by an 18¼in., 260
Camelopardi, two, 101
Camera: bellows, 224
  conundrum bellows, 287
  photo., 554
  stereoscopic, 270, 335
Canada and the transit of Venus, 309
Canaries: cayenne feeding of, 245, 267
  rearing, 271, 291
Canary, asthma in, 270, 291
Cancer, suspected variable stars in, 427
Cancri, zeta, 101, 151, 152
Canes: maj. and min., suspected variable stars in, 427
  venatici, suspected variable stars in, 427
  — (25), 260, 349
Canis minoris (P vii., 173), 171
Canoe: canvas, 246, 268
  folding, 291
Cans, waste tin, 602
Canvas: artists', 37
  boat, 506
  canoe, 246, 268
  for oil painting, preparing, 13
Capricornus, suspected variable stars in, 427
Carbon: bisulphide of, prism, 578
  electro-deposition of, 577
  resistances, 264
Carbons: connections of, 382, 400
  coppering, 381, 430
  cutting, 283
  for Leclanché, 43
  pure for the electric light, 232
Cardboards, bronzing, 531, 553
Cards, cement for (cloth), 223
Carnivorous, how animals became, 493
Carpenter, the Indian, 450
Carpenter's: and mason's level, Turkish, 594
  bench, 289
  saw, sharpening, 407, 504, 528, 552
Carpet, inkstains on, 456
Carriage lamps, railway, 458
Cart and wheelmaking, 187, 252, 562
Casehardening, 315, 337, 362
Cassegrain: Gregorian or, 42, 53, 67, 90
  mirrors of, finding distance between, 172
  telescope, 241, 571
Cassiopeia, suspected variable stars in, 427
Cast: malleable iron, 112
  steel, welding, 338
Casting articles in white metal, 457
Castings: brass, 19
  malleable, 435
  straightening crooked, 515, 573, 597
Castor, 426
Casts, plaster, 337
Cat, the, 1
Catalogue of suspected variable stars, 400, 427, 449, 475, 497, 520, 546
Cataract, 579, 601
Catgut, testing wine with, 519
Cattle, weight of, 16
Cayenne feeding of canaries, 245, 267
Cell: action in the voltaic, 362
  cheap form of voltaic, 5
Cement: Chinese, 455
  for machine carding cloths, 223
  for glass, 135, 138
  for knives in handles, 507
  Portland, for floors, 459, 482
  silicate, 531
  Vulcan, 115
Cemeteries, photographing in, 407
Centre of gravity of a revolving system, 326
Cepheus, suspected variable stars in, 449
Cetus, suspected variable stars in, 449
Chain: putting in watch, 225
  watch fusee, 109
Chair, portable lounge, 457
Change-wheels for screw-cutting, 506, 529, 552, 577, 599
Changing plates, 385
Changing-box for use with dry-plates, 240, 285
Charcoal: converting peat into, 599
  furnace, 89
Chaser, Col. Dumbleton's screw, 1
Chasers with odd threads, making, 29
Chemical balance, 88, 111
Chemistry: address in at B.A., 590
  for engineers, 597
  honours, 553, 578
  institute of, exams., 601
Chemists, to, 505, 528
Chess: 163, 185, 206, 228, 250, 272, 294, 317, 340, 366, 389, 414, 437, 461, 485, 509, 533, 558, 581, 606
Children, illegitimate and will, 505
Chime clock making, 307, 381, 402
Chimney: on girders, 383
  rusting, iron, 431, 455, 504
China, coal in, 568
China, riveting, 546, 603
Chinese cement, 455
Chromograph, 410
Chronometer: half, 270, 278, 311, 335
  rating, 313
Chronology of telephonic discoveries, 584
Chrysoide, 37
Chuck: combined oval and eccentric, 55, 83, 107
  dog, for lathe, 314, 336
  drill, improved, 49
  — simple, 402
  four-jawed, 239
  oval, 36, 38
Chucks: drill, home-made, 323
  wire and small screws for metal-work, 251
Churchwardens, 358
Circle, area of segment of, 8
Circles, areas of, 171
Circuit, telephone, 42, 67, 110
Circular saw, 88, 157, 198, 246, 407
Circulating decimals, 386, 409
Cistern: closet, 41
  question, 603
City and Guilds Institute, Science at South Kensington and the, 527
Civil service, science and the, 12
Clamond's incandescent gas-light, 514
Clarionet, 411, 433, 456
Clark's process for softening water, 457
Clay tobacco pipes, tipping, 66
Cleaning: and repairing watch, 24, 73, 95, 166, 188, 210, 254, 277, 301, 371, 417
  flowerpots, 17
  furniture, 383,
  geneva watch, 40
  watch, 531
Climate for astronomical observation, 9
Clock: American, taking apart, 43, 68, 134
  and carillons for Bombay university, 587
  and watchmaking, 43
  battery for electric, 457
  chime, making, 307, 381, 402
  curious, 40
  dial, painting, 532
  electric, to beat minutes, 39
  electro-magnetic, 263, 283, 330, 358
  illuminating, 432, 455, 528
  "nutmeg," 457
  Reid's self-acting, 231
  tell-tale electric, 181
  to strike quarter-hours, 409
  trains, calculating, 157, 177
  wheels, fitting new teeth to, 332, 354
Clocks: gravity, 69
  gravity escapement, 500, 550
Clock-wheel, cutting engine, 506
Closet cistern, 41
Cloth: American, 180
  tracing on, 527
  waterproof, 182, 200
Clothes, bleaching, 224, 244, 358
Clothing, waterproof, 333
Cloud west of Mare Crisium, 326
Club, amateur dramatic, 17, 39
Coal: atmospheric air required for combustion of, 329, 338, 360, 458
  in china, 568
Coal-tar: products, 60, 242
  soaps, 106
Cobalt, metallurgy of nickel and, 516
Cockroaches, 236, 246, 268
Cocoa, manufacture of soluble, 12
Cocoa-nut oil, 481
Cod-liver oil, 106, 212, 246, 268, 288
Coffer-dam, 530
Coil: and vacuum tubes, 433, 453
  difficulty with, 359, 454, 457, 528
  Gaiffe's medical, 385
  induction, 14, 16, 88, 136, 267, 334, 358, 482, 529, 598
  intensity, 42, 201, 224
  largest, 579
  medical, 41, 247, 289, 313, 482
  Ritchie's induction, 552
  shocking, 435
Coils: batteries and, power of, 529
  cheap resistance, 307
  wire for induction, 603
Coin brooches, 290
Coke, gas, ovens heated by, 132
Cold soldering, 81
Cold-air engines, 87
Cold-water soap, 549
Collieries, explosions in, 360
Colliery explosions, cause of, 6
Collodion: balloons, 292
  dry, 507, 530
Colour: 429, 477, 499, 524, 549, 575, 598
  for terra-cotta, 334
  philosopher's white, 405, 453
Coloured glass, 39
Colouring: gold, 467, 483
  steel without heat, 552
Colours for confectionery, 329
Coma Berenices, 150, 260, 349
Combination machine, 478
Combustion: flameless, 445
  fuel and, 60
  of coal, 329, 338, 360, 458
Comet Wells: 100, 126, 150, 193, 216, 236, 259, 281, 305, 326, 349, 377, 425, 427, 449
  on the photographic spectrum of, 375
Comets: and a committee, 377
  and meteors, 54
  on, 27
  tails, 516
  the search for, 79
Comet-seeking, 281
Communication, electric, 38
Commutator for intermittent action, 386
Companion, microscopist's, 330
Comparison of star magnitudes, 54
Compasses, ships', 291
Compensated watches, 288, 312, 334
Compound engine, Kirk's double expansion, 113
Conacre, sowing, 507
Concave lenses, 458
Concentric microscope, the, 309, 330, 356
Concertina, putting steel tongues to, 386
Concrete: 597
  bed for engine, 271, 291, 313
  walls, 201
Condenser, electric, 244
Coned v. grooved pulleys, 136
Confectionery, colours for, 329
Connecting-rods, grinding spherical-ended, 542
Connections, battery, 290, 382, 400, 410, 433
Connolly's telephone exchange, 94
Conservation of solar energy, 459, 521, 550
Conservatory, a question for spectrum analysts, 314, 337
Continuous brakes: 10, 36, 83, 109, 159
  bill, 311
  Mr. Reynolds's book on, 439
  return, 109, 155, 595
Continuous-ringing electric bell, 132
Contracted finger, 430
Conundrum bellows front camera for 18 dry quarter plates, 287
Copper: analysis of refined, 54
  boiler, riveting, 113, 158
  hardening, 271, 291
  plate, 531
  salts, 68
  sheets, tinning, 362, 430
  sulphate of, 17
  tubes, bending, 434
Coppering carbons, 381, 430
Coral, growth of 363
Corn cures, 348
Cornea, opacity of the, 62
Corona Borealis: 349
  suspected variable stars in, 449
Coronæ, sigma, 570
Corridors of time, glimpse through the, 328
Corrosion, boiler, 482
Corvus, suspected variable stars in, 449
Cottage building, 383
Cotton: 549, 555, 600
  bleaching, 288, 334
  wadding, 179
Cough, why we, 301
Coulomb's law of electro-statics, 458
Counting apparatus, automatic, 381
Couplings: universal for continuous brakes, 156, 202, 265
  waggon, and railway accidents, 574
Court, lawn tennis, 458
Courts of justice, oaths in, 265, 269
Coventry tricycle with Westropp seat, 402
Craters, lunar, 133
Cream separators, 42
Crisium, cloud west of Mare, 326
Crooked castings, straightening, 515, 573, 597
Crossbow, 531
Crossing, Williams's, railway, 578
Crown glass: achromatic telescope, a, 273, 343, 352, 402, 536
  achromatism, 504, 549, 593
Crutches, 337
Crystal Palace electric exhibition: railway signalling appliances at, 23
Crystallising vessels for Epsom salts, 458
Cup and ball microphone, 386
Curious clock, 40
Current: battery, measuring strength of, 160
  electric, 292, 314
  — measuring, 603
  meter, Edison's, 277
  secondary in one direction, 18
Curvature and refractive index, measurement of, 469
Curved forms, production of by link attachment to slide-rest, 9
Curves: of efficiency in the steam-engine, 47
  railway, 270
Cuthbert's compound lever hammer, 166
Cuts and bruises, 269, 290
Cutter: and drilling instrument, combined eccentric cutter and, 11
  bars and slide-rest tools, 415
  new lawn-edge, 542
  universal, 108, 154, 196
Cutting: balance wheel, 530, 553
  carbons, 283
  frame, 196, 218
  mount, 160, 180
  screw-threads with slide-rest only, 357, 381
Cuttriss electro-motor, 587
Cygni, delta, 326
Cygnus: Birmingham's new variable in, 474
  suspected variable stars in, 449

Cylinder: face, repairing, 41
  watch, 457, 505
Cylinders: model engine, 603
  proportions of in compound engines, 410

DAGUERRE and his discovery of the development by vapour of mercury, 476
Daguerreotype, faded, 483
Dancing figures, electric, 161, 180
Dangers, electric light, 177, 194, 238
Daniell's battery, 13, 202
Darkness, forms of light and, 544
Dark-slide, cheap and efficient double, 10, 59
Dark-slides, cheap, 85
Darwin, C., an example of the scientific method, 241
Date-mark, 181, 199
Datum, Ordnance, 434
Daturine, coloured reaction of atropine and, 519
Dawkins, Prof. Boyd, on the ancient world, 31, 52
Days, points of sunrise on longest and shortest, 236, 281, 326, 377
De mortuis nil nisi verum, 192
Dead black for brass, 603
Deafness: 106, 430, 455, 481, 501
  and vegetarianism, 599
Death not universal, 512, 597
Decayed teeth, stopping for, 202, 247, 312
Decimal of the year, 425
Decimals, circulating, 386, 409
Deck of yacht, 136, 158, 199, 243, 266
Declination, moon's, 425
Decorating organ-pipes, 361
Deed of gift, 155
Degree: mus. bac., 292, 336
  of longitude, length of, 150, 161
Delphini, beta, 8, 101
Delphinus, suspected variable stars in, 449
Deodorising paraffin, 531
Depositing trough, 312
Detector: simple and cheap fire, 310, 404
  thief, 386
Developer: dry-plate, 363, 385, 577
  ferrous oxalate, 292
Developing tins, enlargements and, 203
Development, oxalate, 266
Dewcap, 458, 474
Diabetes, 310, 478, 529
Diagram measurer, indicator, 97
Diagrams of oscillating engines, 383
Dial, clock, painting, 532
Dials, watch, 435
Diamonds, glazier's, 385
Diaphragm, iris, for varying aperture of microscope objectives, 25
Dietary, anti-fat, 454
Dietz's improved punch, 78
Diphtheria, 287
Diplomas, chemical, 603
Discoloration: of bricks, 18
  of paint, 181
Disease: potato, 134
  skin, 106, 130, 158, 179, 239, 310
Disinfection, 287
Distillation, 601
Distributing electrical energy, Perry's method of, 539
Dividend, liquidation, 595
Dividing: apparatus, 290
  machines, Ramsden's, 104, 131, 153
Divining-rod, torpedo detector and scientific, 411
Division plate: 161, 176
  for lathe, the construction of which prevents one being made on pulley, 306
Dog-cart, revarnishing, 245
Dog-chuck for lathe, 314, 336
Dome, Vienna, Mr. Scott Russell and the, 357, 380, 451, 476
Domestic: electric lighting, 50
  smoke-consuming stove, 263
Door-fastener, portable, 445
Door-plates, composition for, 291
Double: object-glasses, 151
  stars, 8, 101, 150, 260, 593
  steam-chest, 359
  tricycle, 332, 379
Double star: measurement, difficulty of, 260
  observation in twilight, 474
  work performed by an 18½in. Calver reflector, 260
Down-draught brick kiln, 312, 358, 406
Draco, suspected variable stars in, 475
Draconis, mu, 570
Dramatic club, amateur, 17, 39
Drill: 158
  chuck, improved, 49

Tides, Sir W. Thomson on the, 588
Timepiece, drum, 65, 110
Timing French or other pendulums, 288
Tin: cans, use for old, 459, 602
  dishes for photographic purposes, 135
Tinning: bicycle spokes, 64
  copper sheets, 480
  or bronzing small castings, 271, 291
  steel wire, 338
Tin-plate working, 601
Tin-plates, 361
Tinpot battery, Bennett's, 5, 107, 127, 270
Tires, bicycle, 554
Tobacco-pipes, tipping clay, 66
Tolman's sal-ammoniac cell, 61, 107
Tombstones, lettering, 267
Toning: 159
  platinotype prints, 89
Tonsils, enlarged, 10
Toolholder, makeshift, 218
Tools for bending iron, 36
Torpedo: Brennan's, 444
  detector and scientific divining rod,
Tortoiseshell, 89, 135
Towns, fortified English, 100, 112
Tracing on cloth, 527
Traction engine, 434
Tractrix screw propeller, 495
Train telegraph, 511
Trains for clocks, calculating, 157, 177
Tramcars, jointed axle for, 459
Tramway into gravel-pit, 338
Transfer-paper, black, 483
Transfers, autographic, for printing purposes, 166
Transit: Instrument, 488
  of Venus, 17, 377, 425, 474, 506, 529
  — Canada and the, 309
Transmitter: Blake, 221, 244, 267
  telephone, 43, 87, 289, 313, 336, 338
Transparencies: gelatino-chloride of silver, 146
  glass, 64, 85, 528
  photographic, 15
Transparent: gum, 458
  photographs, 506
Trap, steam, 68
Trapezium of Orion, 8, 474
Trees, grafting fruit, 64
Tremulant, organ, 480
Triangulum, suspected variable stars in, 546
Trichinæ in salted meats, 512
Tricycle: brakes, 526
  Coventry, with Westropp seat, 402
  cranks, 160
  double, 332
  handpower, 85
  seat, Mr. Jeffrey's, 428
  skate, American, 562
  speeding, 169
  steam, 255
Tricycles: 9, 36, 310, 410, 433, 456, 476, 503, 528
  electric motor for, 387
  worked by gas, 597
Trigonometry, 602
Triple expansive engines, 141
Trough, depositing, 312
Trustees, wills and, 241, 595
Tuberculosis: bacillus of, 378
  Prof. Tyndall on Koch's theory of, 168
Tubes: durability of, 411
  vacuum, 411
Tuning: organ, 156
  piano, 159
Turbine for low fall, 64, 85
Turkish: bath, 130, 157, 181, 354, 378
  — "Gereb Admi's," 378, 403
  — heating room for, 289
  carpenter's and mason's level, 594
Turning: calender rollers, 68, 87
  irregular forms, Northcott's apparatus for, 596
  ornamental, 11, 35
  — specimen of, 487
  wooden balls, 13
Turnstiles, 17
Twilight, observation of double stars in, 474
Tyndall, Prof., on light, sound, and heat, 53, 90, 115

UNDERGROUND waters, report on, 591
Unipolar induction, 555
Universal: couplings for brakes, 156, 265
  cutter, 108, 154, 196
  joints in shafting, 12, 110
Unseasoned wood in furniture, 113
Unwritten history and how to read it, 588
Uranus in a 2¾in. telescope, 8
Ursa major and minor, suspected variable stars in, 546
Ursæ majoris, eta, variable star, 126, 474
Ursæ minoris, two, 100

VACUA, Sutton's apparatus for the rapid production of high, 34
Vacuo, electric arc in, 301
Vacuum; brake, G.W.R., 312, 334
  — Gresham's automatic, 108
  — Westinghouse automatic, 195
  brakes, 111, 405
  pump, 334, 528
  tubes and coils, 411, 433
Value of lease, 225
Valve: setting loco., 338
  slide, 64, 68
  throttle, 12, 63
Vapour bath: "Gereb Admi's" Turkish or, 354, 378
  hot-air or, 384, 451, 597, 599
Variable: stars, 31, 150
  — catalogue of suspected, 400, 427, 449, 475, 497, 520, 546
  — in Cygnus, Birmingham's new, 474
Variations: of gravity, 490
  of speed on steep gradients, 380
Varicose veins, 194
Varnish: black, 480, 579, 601
  for negatives, 362, 408
  for Venetian blinds, 201
  for violin, 113
  photo, 385
  removing old, 435, 457
Varnishes and stains, 334, 577
Varnishing: 313
  carriage, 505
  chairs, 246
Vats, leaking, 552
Vegetarianism: deafness and, 505, 599
  sleeplessness and, 574
Vegetable: black and spontaneous combustion, 16
  microscopy, staining fluids in, 210
Vellum, bookbinding in, 386
Velocipedes: 152
  — improvements in, 320
Velocity: of discharge from pipe, 110
  of water in sewers, 109
  of wind, 413, 483
Venetian blinds, varnish for, 201
Ventilating weaving shed, 334
Ventilation, 530
Ventilator, roof, 358
Venus: amateur observations of transit of, 8, 377, 425
  transit of, and earth's distance, 17, 377, 425, 474, 506, 529
  — Canada and the, 309
Vertical shaft, 313
Vibrations: string, 197, 238, 524, 550, 574, 594
  telephonic, measurements of, 514
Vienna dome, Mr. Scott Russell and the, 357, 380, 451, 476
Vinegar, tests for mineral acids in, 248
Vines, mildew on, 411, 456, 505, 529
Violin: Berliner, 309, 332, 385, 404, 427, 481, 591, 594
  muted, 548
  soundboard, wood, 62
  taking top off, 579, 601
  varnish for, 113
Violoncello, beat in, 15
Virginis: alpha, gamma, 426
  gamma, variability of, 100
Virgo, suspected variable stars in, 546
Vision, a blind man's, 398, 451, 502
Visitation, Greenwich, 302
Voice, the, 336
Voltaic: and storage batteries, recent improvements in, 492
  cell, action in, 362
  — cheap form of, 5, 270
Voss electrical machine, 573
Vulcan cement, 115
Vulpecula, suspected variable stars in, 546

WAGES, 266
Waggon couplings and railway accidents, 574
Wall-papers, arsenic in, 386, 528, 549, 577
Walls: concrete, 201
  staining, and plain decorations, 358
Walnut, staining, 246
Wardrobe, polishing, 602
Warranty, piano, 291
Wash for funnel, yellow, 12
Washing-machine, 361
Wassell, Mr., speculum testing, 310, 380
Watch: and clock repairing, 24, 73, 95, 103, 119, 165, 187, 210, 254, 277, 300, 371, 417

Watch: balance-springs, 181
  cleaning, 40, 65, 531
  compensated, 312, 334
  construction, 435
  cylinder, 435, 457, 505
  escapement, 179
    — pendulum, 160
  fusee chain, 85, 109
  jewels, 311
  jobbing, 109
  mainspringing, 100, 174, 247
  mandrel, 266
  putting chain in, 225
  rating, chronometer and, 313
  repairing, 101, 127, 174, 203, 210, 254, 277, 292, 300, 483, 506
  Swiss, 247
  trains, calculating, 157, 177
Watches: dials of, replacing, 435
  questions about, 10
  rates of, 36
Watchmaking, clock and, 43
Water: analysis of, 246
  Clark's process for softening, 457
  expansion of through absorption of gases, 51
  filtering, 66, 507, 530
  flow of from pipe, supposed phenomenon with regard to, 311, 381
  gauging, 68
  hardness of, 54
  heating, 137
  in gravel-pit, 248, 269, 289
  iron in, 384
  measuring flow of, 529, 530, 577, 600
  motor, rotary, 136
  pipes, rusty, 433
  power and electric light, 113
  — utilising, 136. 480
  pressure of, 12, 89, 113
  raising, 247
  softening hard, 507
Water: supply, 66
  velocity of in sewers, 109
Water-closet nuisance, 203, 225
  seats, 600
Water-closets, door-action, 142
Water-gas locomotive, new, 476
Water-hammer action and earthquake phenomena, suggested analogy between, 146
Waterproof cloth, 182, 200, 333
Waterproofing fabrics, 224, 267, 333
Waters, report on underground, 591
Waterwheel: 12
  grease, 505
  hydraulic ram or, 38
  power of, 244
Watt's parallel motion, 247, 238, 318
Waves: height of, 36, 506
  throwing oil on, 550
Wax, paraffin, 135
Way, right of, 192, 201
Weakness, 380
Weather: forecast, 404, 425, 474
  observing, in Northumberland, 349, 570
  superstition, curious, 519
Weaving, wire harness for, 431, 454
Weaving-shed, ventilating, 334
Webb's map of the moon, 9
Wedge photometer, Prof. Pickering on the, 425
Weight: of cattle, 16
  of girders, 387, 409, 507
  of locomotives, adhesive, 13
  of metal by measurement, 137
Welding: cast steel, 338
  theory of, 543
Well: artesian, 449
  remarkable gas, 413
Wells' comet: 100, 126, 193, 216, 237, 326, 349, 377, 425, 449
  photographic spectrum of, 375
  seen at Midday, 461
Wenham's and Watson's microscope stands, 237
Wenham's universal inclining and rotating microscope, 143, 195, 217, 237, 260, 282, 356
Werrington Junction and Ely accidents, 524
Westinghouse automatic vacuum brake, 195
Wet-bulb thermometer, 408
Whales, 50
What shall I do with the microscope? 282
Wheatstone bridge, 85
Wheel: cart and making, 186, 252, 562
  paradox, 262
  putting new hub to, 111, 158
  skates, 246
Wheel-cutting frame, 127
Wheel-grease, 387
Wheels: bevel, 223
  emery, 203
  fitting new teeth to watch and clock, 332, 354
  pressure on railway, 159
White, philosopher's, 405
Whitelead, 111
Whitewashing, 603
Whitworth scholarships, 483
Wide-angle objectives, 283
Wife: liability of, 155
  ruinous, 155, 159
Wildbad: and its cures in Black Forest, 353, 380, 406, 483
  baths of, 552
Will, 575, 595
Willans engine, the, 428
Willow baskets, bleaching old, 483
Wills and trustees, 241
Wind: pressure of, 478, 501, 527, 550, 596
  velocity of, 413
Windmill pump, 288
Window light, 575
Winds, 408
Wine: from beetroot, 561
  rhubarb, 600
  testing with catgut, 519
Wire: chucks and small screws for metal-work, 25
  for induction coil, 602
  gauge, Birmingham, 14, 110
  — French, 89
  hardening brass, 41
  harness for weaving, 431, 454
Wires, fixing electric, 160, 179
Woman, married, will and, 595
Wood: bending, 15, 384, 599
  shrinking, 483, 553
  unseasoned, in furniture, 113
Wooden balls, turning, 13
Work done by an 8·5 Browning-With reflector, 349
Workmen, Indian, 286
Workshop, electric light for, 458
World: at the advent of man, 31
  Boyd Dawkins on the ancient, 52
  largest locomotive in the, 285
Worsted and woollen yarns, 88
Wrinkles, shop, 29

'XTRAORDINARY Challenge, 530

YACHT, deck of, 136, 158, 198, 243, 266
  small, 244
  steel, paint for, 236
Yarns, worsted and woollen, 88
Year, decimal of the, 425
Yeast, preserving, 424
Yellow stains on gelatine negatives, 135

ILLUSTRATIONS.

ACHROMATIC: eyepieces, Steinheil's, 570
  object-glass, the, 490
  telescope, a crown glass, 273, 313
Adjustment of mirrors, 11
Advances in photography, recent, 446, 472, 495
Altazimuth and equatorial mounting, new combination of, 306, 402
American: organ, action for sub-bass, 285
  — two-manual, 219
  tricycle skate, the, 562
Apparatus: automatic counting, 381
  gymnastic, 505
  spiral, 367
Archæological, 580
Astronomical: and terrestrial telescope, 88
  eyepieces, 259
  optics, 193
Automatic counting apparatus, 381

BACILLUS of tuberculosis, 378
Backstays for lathe, 175
Balance springs, 111
Balmer's and Phillip's gas-stoves, 225
Barney's improvements in telephones, 370
Barometer, simple, 218
Bath, Turkish, 161, 355, 378, 403
Batteries, fitting up, 18
Battery: bichromate, improved, 400
  — powerful, 268
  Bunsen, cheap form of, 263, 430
  carbons, connections for, 383
  cascade bichromate, Higgins's, 175
  Leclanché, connections of, 263, 290
  plates, mechanical action for lifting, 246
  simple form of storage, 284
  Tolman's sal-ammoniac, 61
  zincs, mechanical action for lifting, 246, 289, 313
Beaumont's photographic shutter, 382
Bearing, new, for bicycle back-wheel, 63
Bearings, adjustable roller, 330
Bellows: camera, 224
  for brazing, 365
Bells, electric, connecting up, 180
Belpaire locomotive firebox, 86
Berliner violin improvement, 591
Bichromate battery: Higgins's, 175
  improved, 400
  powerful, 268
Bicycle: back wheel bearing, new, 63
  head, self-steering, 346
  hubs, drilling, 551
Binding screws, 182
Blake transmitter, 224
Block, Smeaton's, 426, 450, 475
Blowing, harmonium, 152
Boat-making, canvas, 506
Boiler: for model steamboat, 61, 87, 101, 359, 578
  locomotive, 482
  making, 203
  model locomotive, 577
  plates, punches for, 203
  riveting copper, 158
  vertical, 555
Bolton range-finder, 298
Bookcase, how to make a cheap and ornamental, 34, 175
Booth's shaping attachment, 35
Brake: for omnicycle, 266
  Great Western vacuum, 312
  Gresham's automatic vacuum, 108
Brakes, universal couplings for, 265
Brick-kiln with down-draught, 407
Bristol and Exeter locomotives, 267
Brooches, coin, 291
Building, cottage, 383
Bullet, flight of, 336
Bunsen battery, cheap form of, 263, 430
Burglar alarm platform, 379

CALCULATING machine, Huxley's, 56
Caledonian engines, 136
Call for telephone, 111
Camera bellows: 221
  conundrum, 287
Cancri, zeta, 152
Candelabra in black-wood and ivory, 487
Canis minoris (P. VII., 173), 171
Canvas boatmaking, 506
Carbon connections for battery, 283
Carpenter, the Indian, 451
Cart and wheel-making, 562
Castings: green sand basin for, 443
  straightening crooked, 515
Chair, portable lounge, 457
Changing box for dry-plates, 210
Charcoal furnace, 89
Chaser, Col. Dumbleton's screw, 1
Chaster's electro-plating apparatus, 61
Chime clock, making, 307, 402
China, riveting, 547
Chuck: combined oval and eccentric, 56
  four-jawed, 240
  — dog, 314, 336
  oval, 38
  Reid's drill, 49
Chucks: home-made drill, 323
  wire, and small screws for metal work, 251
Circular saw: 158
  taking buckles out of, 407
Clamond's incandescent gas-light, 514
Clock: chime, 307, 402
  curious, 40
  dials, electric, to beat minutes, 39
  electric tell-tale, 181
  new electro-magnetic, 263, 330
  Reid's patent self-acting electric, 231
  wheels, fitting new teeth to, 333, 354
Coal-tar products, 61
Coffer dam, 530
Coil: condenser for, 244
  induction, 15, 16
  — as an instrument of research, 120
  medical, 313
Coils, cheap resistance, 307
Coin brooches, 291
Coke, ovens heated by gas, 132
Combination machine, 478
Comet Wells, 237, 378
Commutator, electric, 386
Companion, the microscopist's, 330
Condenser for coil, 244
Condensing exhaust steam, 481
Connecting-rods, grinding spherical ended, 542
Connections for carbons, 263, 290
Connolly's telephone exchange apparatus, 94
Conundrum bellows front camera, 287
Copper boiler, riveting, 158
Cornwall, the locomotive, 285
Cottage building, 383
Counting apparatus, automatic, 381
Coupling, the Westinghouse, 196
Couplings, universal, 265
Cream separators, 42
Crossing, Williams's railway, 578
Crown-glass achromatic telescope, 273, 313
Current, electric: measurement of, 89
  production of, 314
Curvature and refractive index, measurement of, 470
Curved forms, on the production of by means of a link attachment to the slide-rest, 9
Cuthbert's compound lever hammer, 166
Cutter: combined eccentric and drilling instrument, 12
  new lawn edge, 512
  universal, 108, 196
Cutter-bars, slide-rest tools and, 415
Cutting frame, 196
Cuttriss electro-motor, 587
Cylinders, watch, 505

DANCING figure, electric, 180
Dark slide, cheap and efficient double, 10
Desk, photo retouching, 215
Destroyer, Ericsson's torpedo boat, 118
Detector: simple and cheap fire, 310
  thief, 386
Diagram measurer, indicator, 97
Diagrams of oscillating engines, 383
Diaphragm, iris, for varying the aperture of microscope objectives, 25
Dietz's improved punch, 78
Dividing machines, Ramsden's, 101, 132, 153
Division plate: fitting to lathe, 90
  for lathe, 306
Dog-chuck for lathe, 314, 336
Domestic smoke-consuming stove, 263
Double-head lathe for sliding two shafts at once, 467
Drill, 158
Drill chuck, Reid's, 49
Drill-chucks, home-made, 323
Drilling: bicycle hubs, 551
  instrument, combined eccentric cutter and, 12
  machines, 111
Drop shutter, 269
Drum timepiece, 65
Dry plates, changing box for, 240
Drying: box, rapid, 225
  moulds, 494
Dumbbell exercise, 360
Dumbleton's, Col., screw-chaser, 1
Dynamo-machine, Griscom's, 464
Dynamo machines: notes on, 81, 152, 261, 330, 382, 479, 523
  small, 354

EARTH and moon, relative motions of the, 281
Eccentric: chuck, combined oval and, 56
  cutter and drilling instrument, combined, 12
Eclipsed sun, 165
Electric: bells, connecting up, 180
  commutator, 386
  clock dials to beat minutes, 39
  — Reid's patent self-acting, 231
  current, production of, 314
  currents' strength, measurement of, 89
  dancing figure, 180
  engine, model, 39
  firing of powder, 201
  light, platinum, 152
  lighting from a photographic point of view, 422
  sign, 41
  skull, 87
  tell-tale clock, 181
Electrical indicator, 455
Electricity, Ohm's laws on, 331
Electro-magnetic: clock, new, 263, 330
  motor, 194, 551
Electro-motor, the Cuttriss, 587
Electro-plating apparatus, Chaster's, 61
Engine: electric, 39
  governors, Girdwood's improvements in, 491
  Otto gas, 145
  — improvements in the, 466
  queries (angular advance, &c.) 360, 384
Engines: Caledonian, 136
  diagrams of oscillating, 383
Engraving machine, 378
Equatorial and altazimuth mounting new combination of, 306, 402
Ericsson's torpedo boat, *Destroyer*, 118
Escapement, three-legged gravity, 131
Exchange apparatus, Connolly's telephone, 94
Exhaust steam: condensing, 481
  injector worked by, 467
Express locomotive, French, 222
Eyepieces: astronomical, 259

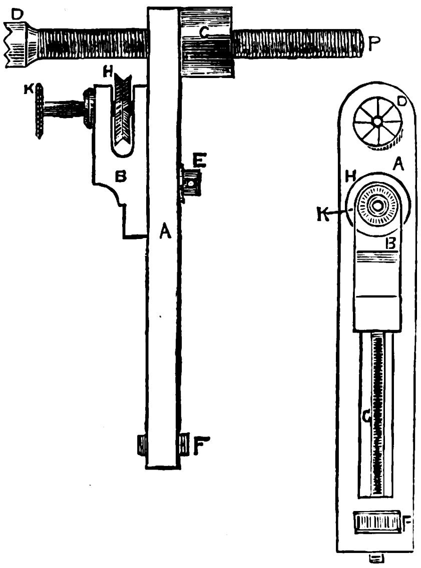
THE ENGLISH MECHANIC

AND WORLD OF SCIENCE.

COLONEL DUMBLETON'S SCREW-CHASER.

A REQUEST has been made in the ENGLISH MECHANIC for a drawing and description of the above. I have therefore sketched it one-half of the full size—viz., 4¾in. long by ¾in. wide and 5-16ths in. thick in the main frame made of brass. This is marked A in the profile and in the front view. This frame is cast with a slot reaching nearly up to C, the cylindrical boss, which slot is accurately worked to 5-16ths in. wide, to receive the tenon of the part B, which slides within it, and which is moved by the screw G and milled wheel F. It can be clamped at any position by the washer and screw E. Through C is fitted the guide-screw D of the desired pitch, which in mine is 20 to the inch; but I believe different ferrules tapped to take screws of other pitch are now made to screw into the boss C. At the end D the screw is finished with a head cut into coarse teeth, by which it is made to revolve when in use. K is the cutter, which is formed as a counterpart of the screw-thread, and is driven from the overhead by means of the pulley H. The end P of the guide-screw has a hollow centre, and rests upon the point of the back poppet, while D rests in a recess turned inside the bottom of the box or its cover. Suppose now a box to have been turned, and D resting in the recess, while P is on the back centre, D being caught by the radial teeth will revolve with the box, causing C and the frame to travel along according to the rate of the screw. A is supposed to lie horizontally on the T of the rest. Now let E be loosened, and by means of F let the screw G draw down the slide B until the cutter K just presses on the outside of the flange or neck of the box on which the thread is to be cut. Attach the overhead, and, while the mandrel is made to revolve by hand, the cutter will form a clean and perfect thread of the pitch of the leading screw. For the inside or female screw, the only difference is that the cutter is arranged inside instead of out. The limit of size of box or other similar article is this: It must allow D to fit inside it, and K to be adjusted outside. A very small article cannot be so managed. The centres of D and K are 11-16 apart when the slide B is at the upper end of the slot, as shown. When at the opposite end they are 2½in. apart. Within these limits any size of work can be screwed to perfection, and the tool is altogether a remarkable specimen of ingenuity. As the leading screw is, *pro tem.*, centred and held securely at both ends, the cutter must be always true and square to the work, so that a slanting or drunken thread is not possible. The thumb-wheel F is merely tapped as a nut to fit the screw G, which latter projects as B is drawn down. The other end is pinned through the slide. It is evident that a deep or shallow thread can be cut according as the cutter is advanced nearer to the work or *vice versâ*. If my old friend and schoolfellow, the inventor, sees this, I hope he will supplement it by giving us other mechanical dodges, as he is a walking dictionary of practical mechanics, with any number of years' experience at home and abroad. My own attention was first drawn to this screw-chaser by a brother-officer of Colonel Dumbleton's, General Cunningham, who also kindly sent me as a present the one I have copied for this paper. It is one of Plant's make, and very well put together. Some will consider the necessity of an overhead a drawback; but the cleanness of cut made by the revolving cutter, and its independent action—the speed at which the mandrel revolves being thus unimportant, quite makes up for the above drawback. It is just the thing for screwing microscope or telescope tubes, where an accurate thread is so important, and for ivory and hard wood nothing can beat it. The only drawback that struck me was having but one pitch of screw; but I wrote to G. Plant, suggesting screw ferrules to fit into C, and that each instrument should be fitted with a set of three screws, 8, 16, and 20 pitch, and was informed that recent ones had been so fitted. Of course, it is easy to turn down to a level after the chasing is finished, the recess made to take the end, D, of the screw. In making this tool, it would be essential that the spindle of K be parallel to the guide-screw, and that the latter stand at right angles to the frame A. I may state, however, that I do not know if this tool is registered or patented, or whether Mr. Plant has a monopoly of manufacture. It is a tool far too little known, and one which deserves especially the attention of amateur mechanics, who would often find it a true friend in need.



O. J. L.

THE CAT.*

"THIS beaste," says old John Bossewell in his "Works of Armorie," "is called a Musion for that he is enemie to Myse and Rattes. He is slye and wittie, and seeth so sharply that he overcommeth darkness of the night by the shyninge lyghte of his eyne. In shape of body he is like unto a Leoparde, and hathe a great mouth. He dothe delighte that he enioyeth his libertie; and in his youthe he is swifte, plyante, and merie. He maketh a rufull noyse, and a gastefull when he profereth to fighte with an other. He is a cruell beaste when he is wilde, and falleth on his owne feete from most highe places, and neth is hurt therewith. When he hath a fayre skinne, he is, as it were, prowde thereof, and then he goeth faste aboute to be scene." Certainly from the day when this quaint description was penned down to the present time, no such exhaustive an account of "the harmless, necessary cat" of the familiar poem has ever been given as that of Professor Mivart, in the book whose title heads our notice. The author's object, as he informs us in his preface, has been to furnish an introduction to Biology generally, more especially, however, to the study of that class of animals to which we ourselves belong—the Mammalia. To this end he has selected the

---

* The Cat: an Introduction to the Study of Backboned Animals, especially Mammals. By ST. GEORGE MIVART, Ph.D., F.R.S. London: John Murray.

VOL. XXXV.—NO. 885.

Cat for description as "an animal easily obtained and of convenient size: one belonging to man's class, and one not so different from him in structure but that comparisons between it and him (as to limbs and other larger portions of its frame) may readily suggest themselves to the student." Now there can be no possible doubt that any one who could, and would, seriously master the 530 pages of Dr. Mivart's book, must rise from its perusal in possession of a very solid groundwork, indeed, for the study of biology generally; whether, though, it is cast in a form either sufficiently popular and attractive throughout to induce any one to do so may legitimately be a subject for discussion. To the student who has passed two or three sessions in dissection in one of our hospitals, the anatomical details given will afford a large amount of information. To anyone of ordinary education, however, who may be induced to take up the subject of biology through the medium of the work now before us, the enormous mass of technicalities which swarm and pullulate all over its pages can scarcely fail to be repulsive. Here and there our author seems to awake to the necessity of rendering his descriptions intelligible to the ordinary layman; and at such times he defines the terms which he is about to employ. Soon, however, he lapses into his seemingly chronic belief that he is addressing a class of medical students, and paragraph after paragraph of utterly crack-jaw and unintelligible terms affords evidence of the fact. Let us, however, examine the work a little more in detail. After a short preliminary chapter, we are introduced to the subject of the general form of the Cat. The chapter devoted to this is succeeded by nine others containing a most minute and exhaustive account of the smallest details of the animal's anatomy. Chapter X., on the Development of the Cat, is very interesting; and would be more so, but for a redundance of that exceedingly technical detail against which we have previously protested. The succeeding Chapter XI., on the Psychology of the Cat, conforms much more nearly to our idea of the manner in which the subject should be treated with which it deals, than do the preceding ones; the cacophonous terminology with which they are filled being here practically discarded, and a very instructive and readable essay on the mental powers and constitution of the Cat being the result. Our chief disagreement with the author in this portion of his work lies in our belief that his assertion that human and brute intellect differ in kind is a fallacious one. That their diversity in degree is enormous, few, we apprehend, would be concerned to deny. That, on the other hand, any difference between them in kind exists, hardly anyone now, we conceive, would be ready to admit. We trust that we are doing Dr. Mivart no injustice in the assumption that some theological exigencies are at the bottom of the views which he advances. The manner in which he elsewhere cites Aristotle seems to lend considerable force to this idea. Unquestionably, the great Stagyrite did good service both to the inductive and deductive methods of inquiry; but it must not be forgotten that he wholly ignored the need of the method of verification, and was very very far from himself being infallible. Chapter XII., on Different Kinds of Cats, gives an exact and comprehensive description of all known species of Felidæ, recent and extinct; and in the succeeding one, XIII., The Cat's Place in Nature is discussed, and the position of the animal with reference to other orders of animated beings defined. The Cat's Hexicology (or relation to its surroundings or environment) forms the theme of Chapter XIV.; the concluding one, XV., being devoted to the Pedigree and Origin of the Cat. Here again, the quotation of St. Augustine lends colour to the belief that the treatment of the subject is not wholly and entirely *scientific.* Profound and intimate as is obviously the acquaintance of Dr. Mivart with natural history, we venture to think that an adequate knowledge of Physical Science would be of the greatest advantage to him in treating on subjects so extensive as some of those he discusses in the pages of his latest book. On p. 306 he gives the velocity of the electric current quite erroneously, and that of light at nearly one-fifth of its true amount! Furthermore, a protest on his part against force being considered as an entity, would seem pretty plainly to indicate that the Conservation of Energy is a fact of which he is in happy ignorance; or that he has wholly failed to grasp its signification. Having, though, pointed out what we regard as faults—and some of them sufficiently grave ones—in "The Cat," we now must reiterate what we have said above as to its value to anyone who will work steadily through it, and verify what he reads by actual dissection. The fine and numerous woodcuts which illustrate the book no doubt render work with the scalpel superfluous for the general reader; but they will not supersede the necessity for the direct method of experiment by the earnest student. To such a one who will carefully master the contents of Professor Mivart's work, and see practically for himself what it describes, we can unhesitatingly promise a considerable and valuable addition to his store of biological knowledge. We have pointed out the shortcomings of the book quite unsparingly; but with all its faults it will remain as one of the most able and exhaustive monographs in the English language on the subject of which it treats.

THE ORGAN: AND HOW TO MAKE IT.—XV.

By J. Dresser.

The Action-Work (*continued.*)

BUTTONS are used as nuts on the tapped wires to regulate the action. They are made out of good sole leather, and are sometimes punched out with a quarter or five-sixteenth punch, and a centre-hole made with a bradawl; but a much better plan is to get a quarter or five-sixteenth centre-bit, and file off the scraping or scooping side, leaving only the centre-pin and the scoring side. This will cut out, shape, and centre the buttons very nicely, and the only question is whether they can be made or bought most cheaply; but certainly, the home-made are quite as good as the bought. A rather thin, but firm and good, sole leather is required for button-making.

Cloth washers are made by punching with a quarter or five-sixteenth punch. Scarlet cloth is the nicest looking, but any other colour does equally as well; the use of these washers is to prevent noise through the movement of the action work.

Rollers are long bars of wood, generally pine, and are of various sizes, according to their length and the work they have to do. They are usually rounded on the top and bottom sides to allow room for them to work; rollers are also frequently made of iron—sometimes of solid rod-iron, but more frequently of small gas-tubing; when they are made of solid iron they are usually of quarter-inch rod; holes are drilled for the arms which are riveted in, and at each end a hole about an eighth of an inch deep is drilled; into this a screw-pin is adjusted, the screw-pin working through either a wood or iron stud. (Fig. 1) shows the arrangement. Where hollow or gas-tube rollers are used, the rollers are cut to the required length, the holes are next drilled for the arms, then a plug of wood is driven firmly into the end of the roller, the arms may then be either screwed into the wood centre, or they may be riveted in the same way as if the rollers were solid; the centre pins are then used in the same way as for wood rollers. In some cases wood arms are used on iron rollers; when this is done, a hole is drilled through the roller in the usual way. The arm is hollowed out at the roller-end to fit on the roller, and a thin screw is put through the roller into the arm. (See Fig. 2.)

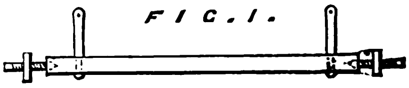


FIG. 1.

FIG. 2.

Roller-studs are little blocks fixed into the roller-board, and project so far that the roller can lie between and be centered into them; in the case of solid iron arms, the studs are either iron or wood, with a screw through the end of the stud, fitting into the hole in the roller; where wood, or hollow iron rollers are used, a hole is bored through the stud and bushed with cloth, a pointed wire is put through the hole, and inserted for about ¾in. into the roller; the wire pin should fix quite tight in the roller, and work easily, but without any looseness in the bushed hole in the stud.

The above are about all the small parts of the action, and the next thing is to put these separate parts together. The one essential idea is this—viz., a key is pressed down by the finger, and a corresponding valve must be opened in the wind-chest; but the means of communication between the key and the valve may be arranged in any manner at the discretion of the builder. A few organs have been built in which tape carried over small rollers was the only movement, and in a room that is kept at, or nearly at, an even temperature, it answers very well, and will last a good many years.

The simplest form of ordinary action is the fan frame, in which the smallest pipe is at the treble, or right hand, and the largest at the bass end. This pattern, however, is not often adopted for small organs, although, after a number of trials, I look upon it as the best arrangement, although some little room is lost at the treble end; but my experience about the size of chamber, and often also of church organs, is this. *Purchaser*—"I can only allow so much room." *Organ Builder*—"I will endeavour to meet your wishes." The organ arrives, and organ builder says, after he has the organ erected, "I should have liked a few inches more, as I have been obliged, slightly, to crowd some of the pipes." Purchaser replies: "If I had thought the organ would look so nice, you might have had another foot." This is only a fair specimen of conversation I have often met with, and I only give it to show the ideas of persons who do not understand organ work; to those who purpose building an organ, I would say, Do not crowd the pipes, or the action work, but give plenty of room.

PRACTICAL NOTES ON PLUMBING.—XXVIII.*

By P. J. Davies, H.M.A.S.P., &c.

Closet-Valves.

VALVES should have a clear-water way or passage through the seating, and the valve should lift at least half the height of the diameter of the water passage through the seating (for the proper lift of valves for the discharge of liquids it is only one-third the diameter; this, however, has nothing to do with the case in point). The instant the lever of the closet-valve begins to descend the valve begins to close, so that the higher the valve is lifted the longer will the water be allowed to run full bore.

Stool-Valves.

The best kind of valve for fixing under the seat of a w.c. is shown at Fig. 148: it is known in the trade as the stool-valve with stuffing-box, excepting that this diagram shows an improvement at M, consisting of the rocking standard instead of its being fixed. Now, were it a fixed standard, the pin at P could not be used, but the lever would then slide through an eye fixed upon the spindle D, as in Fig. 160 at J G L. The parts are as follows:—R is the lever which actuates and governs the valve, A is the inlet, C the indiarubber valve, S the seating, D the spindle working through the stuffing-box F, but may otherwise be made to work an indiarubber or some other flexible diaphragm, in lieu of the stuffing-box (which will be described and illustrated further on at Fig. 160); B is the outlet, which must be connected by a short piece of pipe (see I, Fig. 142, also 143), about 18in. long, to the arm of the closet-basin. This connection is usually made with a putty joint; but in some instances, and not unfrequently, effected by a properly-made soldered joint. These fittings are generally attached to the spreader (this spreader is by some persons wrongly yclept a fan; the proper title, however, is "spreader," inasmuch as it serves to spread out the water into a thin layer over the surface of the basin).

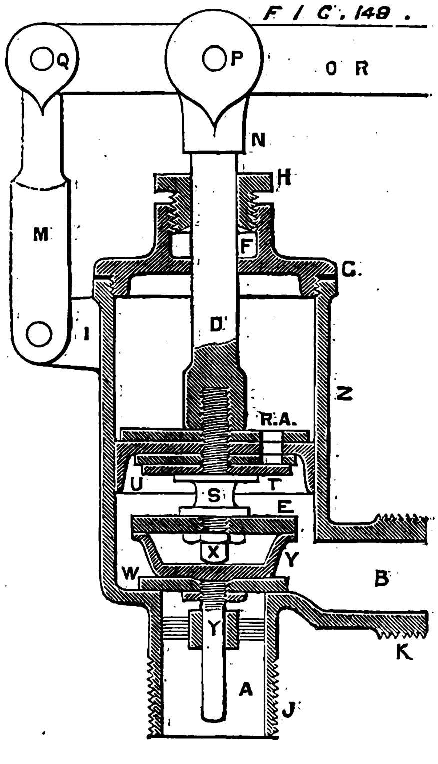
* From the *Building News.* All rights reserved.

Fig. 149 is a representation of the same kind of valve, only that it has some additional working parts which, in my opinion, should be fitted (or their equivalent) to every closet; these parts are for the purpose of retarding the descent of the lever R. This retarding mechanism is simply a solid piston, bucket, or sometimes an indiarubber or other flexible diaphragm is substituted: in this diaphragm is shown a cupped bucket U. The action of this valve is, that the raising of the lever R brings up the piston-rod or spindle D, and with it the inverted cup leather or bucket U; but, on suddenly dropping the lever, the valve T will close and prevent the too quick return of the water from below to above the bucket, so that this would keep the valve V W always suspended from off its seating. This would render the valve useless if not allowed to descend; but to counteract this contingency it is usual to employ a regulator-cock, or something equal thereto—vide Z, C, D (end elevation) Fig. 150; this tap, or other regulator, regulates to the greatest nicety the fall of the lever, also the valve V W, Fig. 149, within a given time, and in proportion to the opening of the water-passage through the tap and from below to above the piston. In this diagram the valve is converted into a waste preventer by the simple use of my "boy's" sucker E, which, on raising the spindle D, and the sucker E, takes up the valve-dish and with it the valve; this valve after a few seconds drops off again, and so closes the valve-seating. Notice: In this case B is the inlet and A the outlet.

FIG. 149.



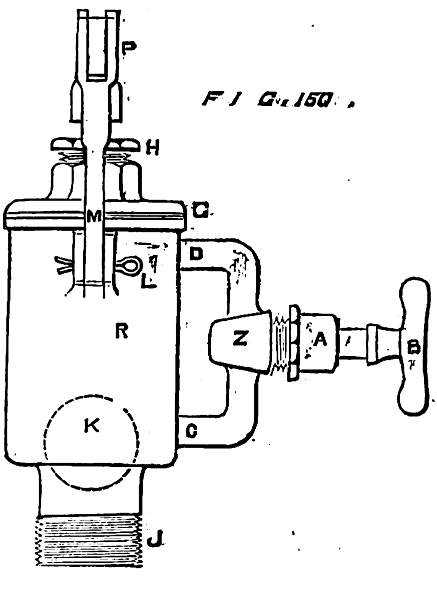


FIG. 150.

Fig. 151 is an elevation of the above valves, showing the lever as weighted at W; it also shows the end of the pull, R S. Fig. 151A illustrates the valve with lugs E, for screwing the valve to wood or brick, &c., as the case may be, also the dish and pull as fixed.

FIG. 151.

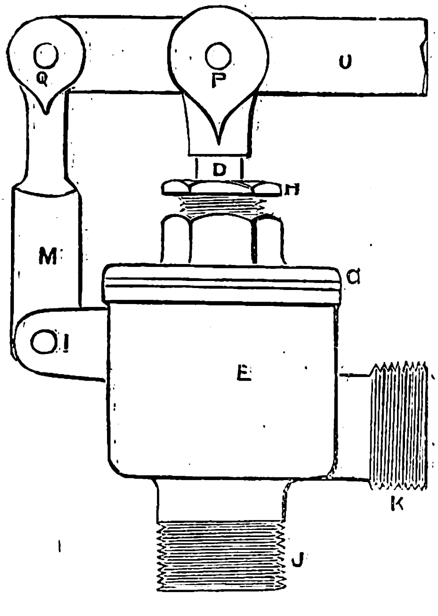

FIG. 151 A

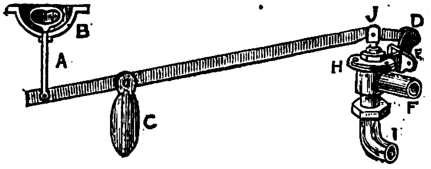

The Waste-Not Closet-Valve, Made by J. Tylor and Sons.

This valve is illustrated at Fig. 152, and works as follows:—R is the inlet; D the valve-seating, P the outlet, B the top part of the valve, H the indiarubber washer, X the screw, with a diminishing or cone-shaped head, which, by the way, answers two purposes—viz., as a screw to hold the washer, and as a reducer for the flow of water through the valve-seating before the valve returns and finally rests upon the seating. A is the regulating screw-valve or cock, to prevent the valve remaining too long open; it also prevents the too-sudden closing of the valve, as illustrated at Figs. 149 and 150. Assume the valve H to be at rest upon its seating D. Raise the lever Q, which will, as exemplified, bring up the spindle T, and the cylinder or socket F, with it also the loose piston B C H off the valve-seating; but, by reason of the slackness of the fit of this piston, it allows the water to pass between its sides from below to above, or into the top of the cylinder E, and in proportion to its size and the amount of fit within these parts, or the distance travelled, so long will the water continue at each upward movement of the lever. My personal experience in the manufacture of these valves led me to make the plunger as large as possible, and to fit easily.

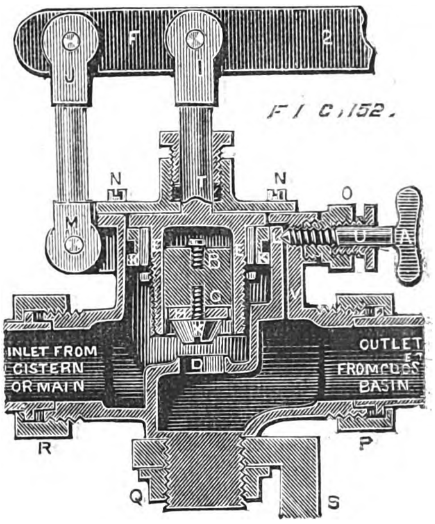

Fig. 153 also illustrates the retarding mechanism F G E fixed below the valve; this kind of retarder has been very extensively used in large Cornish steam pumping engines, and are known by the title of the "Cataract" (*vide* "Bourne on the Steam Engine"). Fig. 153: A is an elevation showing the lever unions and lugs for fixing.

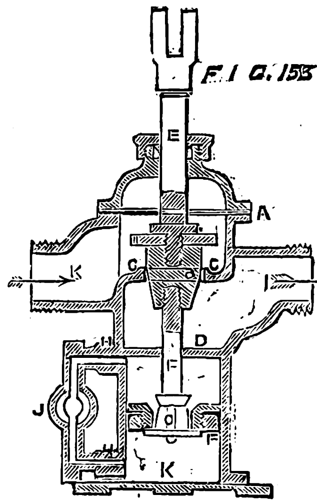

Fig. 154 illustrates this retarding mechanism as manufactured by G. Jennings and some others; but, instead of its being done by the rigid piston, it is here a flexible one (see D, Fig. 154); F is the end of the lever, E the valve-spindle, B the relief-valve to allow the diaphragm to pass one way without hindrance, but

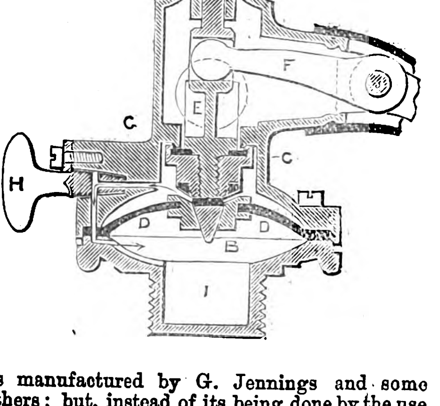
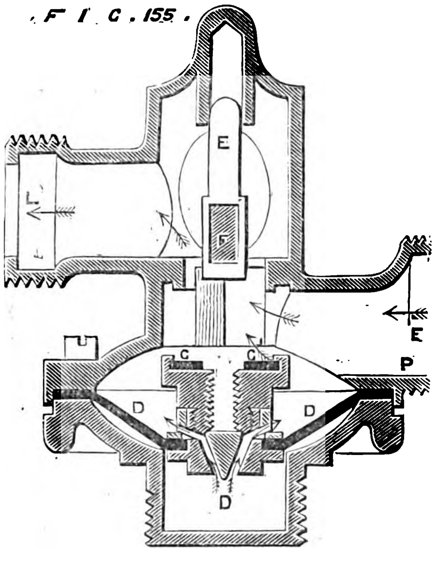
FIG. 154.



which afterwards closes, and so allows the valve to close accordingly as the pass or regulating cock H is opened. Fig. 155 is an end screw of the regulator 154, and illustrates the inlet waterway P, and the outlet L; it also shows the valve G opened.

FIG. 155.



(*To be continued.*)

THE STORAGE OF ENERGY.

LAST week, Prof. W. E. Ayrton delivered a lecture at the London Institutien on the "Storage of Power," in which he referred to the various appliances in use for that purpose, but especially to Faure's accumulator. Among the experiments shown, the lecture theatre was lighted, a circular saw driven, and a hoist for raising boxes worked by means of electric energy which had been stored the previous day in Faure accumulators, and conveyed to the Institution. The total quantity of energy was 50,000,000 foot-pounds—a little more than 25 h.-p. exerted for one hour. We omit the earlier portion, as it refers to matters well understood, and commence with that portion in which Prof. Ayrton describes the theoretical construction of the Faure battery:—In addition to having the plates near together, they must have large surface, in order to store much electric energy. And the way to give the plate a large surface, without making it inconveniently large, is to make it spongy. Hence, what is aimed at is two spongy lead plates near together. Now, Planté made spongy lead plates thus: he placed two or more sheets of ordinary lead in dilute acid, and sent a current from one to the other. This produced brown peroxide of lead on one plate, and liberated hydrogen at the other. After a while the cell was discharged by allowing it to send by itself a current through an external circuit. The effect of this was to reduce the peroxide to spongy lead and to oxidise the other plate, an action which was continued by again sending a current through the cell from an extraneous source, only in this case in the opposite direction from that in which the first charge or current was sent. Reverse currents were now sent in succession for longer and longer times, the cell being discharged between the sending of each, also for longer and longer periods, until at length, after some months, a "well-formed" Planté's cell was the result. To subsequently charge it when required, a current is sent through it in one direction only, and a return current is produced when the cell discharges.

In 1880 M. Faure thought of the device of putting a thick layer of red-lead on his lead-plates, a substance which can easily be reduced to spongy lead by the passage of a current. The plates, after being coated with red-lead, are then wrapped in flannel jackets, and put side by side in a box, every alternate plate being connected together so as to practically form two plates with very large surface very near together. To form the cells, reverse currents are sent somewhat in the same way that they are sent in forming the Planté's cell, with the exception that days only, and not months, are required in the formation. The red-lead on the one side is reduced to a spongy material, which is probably lead very slightly oxidised; on the other side, it is reduced to lead peroxide. Charging the cell by sending a current in the direction of the last current sent reduces the sub-oxide to pure lead, and the lead peroxide on the other side to an even more oxidised salt. On using the cell to produce an external useful current the pure spongy lead becomes again slightly more oxidised and the peroxide slightly less oxidised. In fact, there is a small quantity of oxygen which travels backwards and forwards as the cell is charged and discharged. Now, does such a cell store electricity? No! emphatically no! When charging it, just as much electricity passes out as passes in, and, when discharging it, just as much electricity passes in as passes out. A secondary battery does not store electricity, but electric energy. The pith then of Faure's discovery was the mechanical placing of a salt of lead on the leaden plates, the presence of which layer of lead salt enables spongy lead to be produced in a few days, instead of requiring many months, when the spongy lead is electrically formed out of the lead plates themselves by the long passage of electric currents.

The next point to consider is—1st, the storing capacity of such an accumulator; 2nd, its efficiency; 3rd, its durability. Now I am able to give you more than hearsay evidence on this point, since Professor Perry and myself have been engaged on rather a long series of experiments on this subject.

Let us take a single example of the storing capacity. A certain cell, containing 81lb. of lead and red-lead, was charged and then discharged, discharge lasting eighteen hours—six hours on three successive days; and it was found that the total discharge represented an amount of electric energy exceeding 1,440,000 foot-pounds of work. This is equivalent to one horse-power for three-quarters of an hour, or 18,000 foot-pounds of work stored per pound weight of lead and red-lead. On the second day we made it give out energy more rapidly than the first, and on the third more rapidly than on the second—this being done, of course, by diminishing the total resistance in circuit. During the last day we were discharging with a current of about 25 ampères. But in connection with the storing power there is a very curious phenomenon to which I think not nearly sufficient attention has been directed, and that is the resuscitating power of a Faure's cell. When a cell has been apparently completely discharged, and is left for a few hours by itself, it appears to have obtained a new charge. For example after the 18 hours' discharge just referred to, although there apparently was no electric energy left in the cell, it was found that after a few hours' insulation, the accumulator could give a current of over 50 ampères, and produce, therefore, bright flashes of fire. The phenomenon is wonderfully like the invigorating action of sleep. In one case, during our experiments with an extremely rapid and powerful discharge, we found that in subsequent discharges after rest, the cell gave out three times as much energy as it did in the first discharge. The neglect of considering this resuscitating power has doubtless misled many people who have possibly discharged a Faure's cell very rapidly, into under-estimating its storing capacity. Not getting out, perhaps, so very much energy in the first discharge, they have erroneously concluded that a considerable portion of the energy originally put in had leaked away, whereas, in fact, the electric energy really was remaining there in the cell, but their experiments were conducted too hurriedly to allow it to come out. This resuscitating power may be observed even after very short periods of rest, is of great importance when a large amount of energy is required at the commencement, after periods of rest, as for example in starting a tramcar after each stoppage, which tells most fearfully on the horses. Secondly, as regards efficiency. The efficiency of an electric accumulator—that is, the ratio of the work put into it to the work given out, depends on the speed with which it is charged and the speed with which it is discharged. If charged or discharged too quickly, a certain amount of power will be wasted, heating the cell itself; since, whenever a current passes through a body, some heat is developed, and the greater the currents the greater the heat, the latter, indeed, increasing much more rapidly than the current. Now, it is possible, in a way I will not at the moment trouble you by explaining, to distinguish between the work given to the cell to produce chemical decomposition and the work wasted by too hurried charging. Similarly, in discharging, it is also possible to find out how much of the electric energy stored up in the cell is wasted in heating it by too hurried discharging. Allowing for such unnecessary waste, experience shows that, for a million foot-pounds of charge discharged with a mean current of 17 ampéres, the loss in charging and discharging combined need not exceed 18 per cent.; indeed, in some cases, for very slow discharges, we have found it not to exceed 10 per cent. I do not, of course, mean by this, as some people have mistakenly imagined from the published numbers of Professor Perry and myself, that a current of only 17 ampères can be obtained by discharging a single cell; since, of course, far greater discharge-currents can be produced if the external resistance be low; indeed, I shall show you a constant discharge of about 70 ampères presently. In speaking of the number 17, I merely mean to say that was the average current when the experiments on the efficiency above referred to were made.

I have said that a cell containing 81lb. of lead and red-lead stored 1,440,000 foot-pounds of work. Now, consider what that means. It represents all the energy required to be expended to pull a tramcar containing 46 passengers over two miles, after allowing for considerable waste of power in the electrical arrangements. The electromotor need not weigh more than about 200lb. to produce about two horse-power. We have therefore this wonderful conclusion, that about 300lb. dead weight, contains all the energy and all the machinery necessary for over two miles run of a tramcar with 46 passengers. Now is this result actually obtained at present in the tramcar running at Leytonstone, which is propelled by Faure's accumulators? No, and why? Partly because the electromotor has not been made to suit the accumulators, nor the accumulators the electromotor, nor is the gearing adapted to either. The cells, as at present made, would not give off their energy quickly enough; hence a greater number are employed, but which, consequently, require to be charged much less frequently than would otherwise be necessary. Indeed, in a ton of the cells as at present constructed there is about 50 miles run of a tramcar containing 46 passengers. Spacious as is the Lecture Theatre of the London Institution, it is unfortunately not large enough to admit a tramcar. I have, therefore, done the next best thing to prove to you that the Faure's accumulators really contain a vast store of available energy. We have here a circular saw, which is now cutting wood over an inch in thickness. As you see, the circular saw is driven by that Gramme electro-motor, and the electro-motor itself is fed by the energy stored up in these accumulators, and which was put into them by a dynamo machine yesterday on the other side of London.

The main use of the accumulators will be as stationary reservoirs corresponding with cisterns for water or gasometers for gas. But in certain cases where the accumulators can be used to propel a cart, as in the case of tramcars, not the cart employed solely to carry the accumulators, then there is not the same objection to their being moved about, seeing that the total weight necessary is small compared with that necessary for a steam-engine or a compressed air-engine for tramlines to develop the same horse-power.

Again, just as ordinary electromotors are not made to discharge a Faure's cell rapidly, so ordinary electric lamps are unsuited for this purpose; and, therefore, although there is enough energy in a 100lb. dead weight of Faure accumulator, to give a light of 1,500 candles for 30 minutes, an ordinary electric lamp cannot be illuminated at all by a single cell. Mr. Edison, however, has been turning his attention to this subject, and here is the result of his handiwork, which arrived last night from America, and which is, therefore, shown for the first time in England this evening. This incandescent lamp, as you see, only requires four Faure accumulators to illuminate it, this one 8, and this other one 12. But must the accumulators be even as large as those I am using on the table? The answer is No, if you do not require them to give out the light for a very long time. Four much smaller boxes would give just as much light as you see at the present moment; but, of course, would not keep the light burning so long. It is, therefore, now possible to have a box of accumulators and an incandescent lamp, and the whole thing quite easily carried by one man.

I have, during this evening, been talking of the measurements of electric energy put into or taken out of an accumulator in foot-pounds, and you may have wondered how it was possible to measure electric energy in the engineer's unit of foot-pounds. In reality it is very simple. The maximum amount of work a waterfall can do depends on two things: the current of water and the height of the fall. In the same way, the work a galvanic cell or accumulator can do depends on two things: the current it is producing, and what is called its electromotive force, the latter being analogous with the difference of pressure or head of water. Again, when electric energy is being turned into mechanical work by means of an electromotor, the energy which is being put into the motor can be measured by the product of the current sent through the motor and the electromotive force maintained between the terminals of the motor. Now here I have two instruments devised by Prof. Perry and myself, an Am-meter and a Volt-meter, the one for measuring a strong current, and the other a large electromotive force. With these we will now make simultaneous measurement when we allow this motor, which is driving the lathe, and which is itself driven by an electric current, to run at different speeds. First we will start with the motor absolutely at rest, by putting a brake on it, and ending by allowing it to run as fast as possible.

Experiment performed and the following results were obtained :—

Speed of Motor.	Current in Ampères.	Electromotive Force between terminals of the motor in volts.	Electric Energy put into the Motor in foot-pounds per minute.	Power wasted by the current heating the wires of the Motor in foot-pounds per minute.
0	15	15	$15 \times 15 \times 44{\cdot}25$ *i.e.* 9956·25	$15^2 \times 1 \times 44{\cdot}25$ *i.e.* 9956·25
Slow	10	21	$10 \times 21 \times 44{\cdot}25$ *i.e.* 9292· 5	$10^2 \times 1 \times 44{\cdot}25$ *i.e.* 4425
Fast	4	28	$4 \times 28 \times 44{\cdot}25$ *i.e.* 4956	$4^2 \times 1 \times 44{\cdot}25$ *i.e.* 708

We see in the last case, when the load was light and the speed of the motor very great, there was less than one-tenth of the waste of power arising from the current heating the wires when the speed was very slow. On the other hand, we observe that the electromotive force between the terminals of the motor has been practically doubled. This simple experiment really points to the solution of economic transmission of power by electricity, and to which Professor Perry and myself have on numerous occasions directed attention. It is, to allow only a very small current to pass through the wires connecting the electromotor with the generator, and to maintain a very great electromotive force between them; since, in this way, the amount of power transmitted can be made as large as we like, and the waste from the heating of the wires from the passage of the current as small as we like.

Reasoning in this way, Sir W. Thomson showed, in his inaugural address last year to the British Association, that, if we desire to transmit 26,250 horse-power by a copper wire $\frac{1}{2}$in. in diameter, from Niagara to New York, which is about 300 miles distance, and if we desire not to lose more than one-fifth of the whole amount of work—that is, to deliver up in New York 21,000 horse-power —the electro-motive force between the two wires must be 80,000 volts. Now, what are we to do with this enormous electromotive force at the New York end of the wires? Fancy a servant dusting a wire having this enormous electromotive force. You might as well, as far as her peace of mind is concerned, ask her to put a lightning-flash tidy.

The solution of this problem was also given by Sir W. Thomson on the same occasion, and it consists in using large numbers of accumulators. All that is necessary to do in order to subdivide this enormous electromotive into what may be called small commercial electromotive forces is to keep a Faure battery of 40,000 cells always charged direct from the main current, and apply a methodical system of removing sets of 50 and placing them on the town-supply circuits while other sets of 50 are being regularly introduced into the main circuit that is being charged. Of course this removal does not mean bodily removal of the cells, but merely disconnecting the wires. It is probable that this employment of secondary batteries will be of great importance, since it overcomes the last difficulty in the economical electrical transmission of power over long distances.

I will conclude my lecture by illustrating one of the other important uses to which the accumulator can be applied, and that is the practical lighting of railway trains, which may be seen in daily operation in the Pullman cars on the Brighton line. The most natural method of lighting a railway train would be to attach a dynamo-machine to the axle of one of the carriages, the guard's van for example, and the rotation of which, necessarily very rapid when the train is going fast, would, without the use of any gearing, produce the necessary current. But the difficulty that immediately meets us is that as soon as the train slows, or stops at a station, or in consequence of the signal being against it, the speed of the dynamo-machine will diminish and the lights will go out. If, however, while the train is going fast the dynamo performs two operations, the one to keep the lights burning, the other to charge a battery of Faure's accumulators on the train, then the electric energy so stored can be applied to maintain the lights while the train is going slowly or stopping. With such an arrangement there would be of course an automatic contrivance for disconnecting the dynamo-machine from the circuit when the speed becomes too low: otherwise the Faure's accumulators would simply discharge themselves back through the dynamo machine.

Imagine now we are in a train which is going slowly, or which has actually stopped, and that the Faure accumulator lying on the floor here is the Faure battery in the train, which have been charged when the train was going fast; that then it has sufficient store of power to continue lighting is proved, because, on connecting these two wires, those 50 Maxim lamps and eight Edison lamps before you are instantly brilliantly illuminated, each possessing about 40 candle-power, and giving, therefore, far more light than is, at present, ever supplied to a whole train of twelve carriages. The light, you observe, is perfectly steady, and is turned on and off at will. Imagine now we are in a tunnel in the daytime, and the lights, therefore, burning. We now emerge from the tunnel into daylight. I disconnect the wires, and the lights are instantly extinguished. Again, it may be we are entering a second tunnel. The wires are again connected by the guard, and we have the whole of this lecture-theatre, which represents the train, brilliantly illuminated.

There has been an erroneous impression existing lately that the Faure accumulator could not produce a constant current of more than 17 ampères; but that this is a mistake is clearly seen from the fact that, at the present moment, each of the cells in this room is producing a current of about 75 ampères.

A CHEAP FORM OF VOLTAIC CELL.

THE following details of a cheap and, we believe, new form of voltaic cell are abstracted from a paper by Mr. A. R. Bennett, M.S.T.E. and E., read recently before the Glasgow Philosophical Society. The cell has not yet had a prolonged trial, but it has been tested for some months side by side with the Leclanché—with which it is comparable—and has not exhibited any signs of inferiority either as regards power or durability.

The idea of the combination was suggested by the well-known fact that iron will not rust in solutions of the caustic alkalies, a fact probably due to the non-existence in such solutions of free oxygen and free carbonic acid. It was argued from this that if a plate of iron and a plate of zinc were immersed in such a solution, the iron, not being attackable by the alkali, would be strongly electro-negative to the zinc. Trial proved the idea to be strictly correct. Not only iron, but nickel and cobalt, as well as gold and silver, and the metals of the platinum group, were found to be practically as electronegative to zinc as carbon itself. Carbon is at first a little more strongly electro-negative than iron; but, owing to the absorption of hydrogen in its pores, as soon as the circuit is closed, it is in practice in no wise superior. Silver is the most electronegative of all the metals in the solutions. The use of iron, if practicable, has obviously several advantages. The cheapness of the metal, and its freedom from liability to fracture, as compared with carbon, are strong points in its favour, and it affords, besides, the possibility of making a perfect and permanent connection on the negative plate for the binding screw, an end so difficult to attain when carbon is used. It was discovered, however, that a simple iron plate polarised very rapidly, the hydrogen set free by the action of the battery clinging to it and greatly increasing the resistance. By surrounding the plate with a packet of small fragments of iron, such as clean turnings or borings, in the same manner as the carbon plate in the original type of Leclanché is surrounded by fragments of carbon and manganese dioxide, this deleterious action is considerably modified, and the cell acquires to a great extent the power of keeping up its electromotive force when working continuously through a low external resistance. The number of points presented by the turnings or borings is probably the cause of this, as it is well known that hydrogen escapes with much greater freedom from a rough than from a smooth surface. The greatest efficiency is obtained when the iron fragments are thoroughly damped by the solution, but not immersed in it, the obstacles to the escape of the hydrogen being then at their minimum. Although not quite constant when working through an external resistance of 20 ohms, the battery recovers its original electromotive force when allowed to rest, with a rapidity sufficient to allow of its employment on the busiest telegraphic circuits, and for most other practical purposes. The electromotive force of the iron battery varies somewhat with the nature of the iron and the purity of the exciting salt employed; also with the degree to which the iron fragments are saturated or covered by the solution. The Daniell being 1, and the Leclanché, at its best, 1·30, the iron varies from 1·15 to 1·33. The last was an exceptionally good cell, and the average may be taken at 1·23, or ·07 less than the best Leclanché. But after working for some days continuously through a low external resistance, the iron keeps up its electromotive force much better than the Leclanché.

There is here an old tinned iron can, which, as the legend upon it distinctly states, was originally packed with corned beef in Chicago. There is also here a quantity of iron borings swept from the floor of an engineer's workshop, the cost being simply the time and trouble consumed in sweeping. There is also a strip of common zinc cut from an old roof ventilator; a porous cell, and a bottle containing a solution of 4oz. of commercial potassium hydroxide. The porous cell being placed in the tinned iron can, and packed with borings, the solution is poured in, and the zinc strip immersed in it. The ends of an electric bell circuit being attached to the can and zinc strap, the fact that a powerful current has already been set up is made sufficiently obvious. After a few minutes it will become still more powerful; and if left to itself the cell would ring the bell night and day for at least three weeks without any noticeable loss of energy.

The tendency of the caustic alkalies to absorb carbonic acid from the air renders it desirable, although not absolutely necessary, to keep the porous cell which contains the solution tightly covered. On the other hand, the iron portion of the battery should be exposed as freely to the air as possible to facilitate the escape of the hydrogen. These contrary conditions are rather vexatious, but by no mean impossible of attainment. The most practicable mode of solving the difficulty appears to be the placing of the positive portion of the combination in an earthernware cell about seven inches in height, but porous only for four inches from its bottom, which porous cell is fitted with an air-tight stopper, through which the zinc rod is brought and terminated by a binding-screw. The earthenware cell is placed in an iron can five inches in height and of a like diameter, and packed in firmly with turnings or borings. The earthernware cell having been filled with solution almost to overflowing, the air-tight stopper is fitted in, and the battery is ready for use. The advantages of this arrangement are the exclusion of carbonic acid from the caustic solution while the iron is left exposed to the air, the prevention of evaporation, and the preservation of the packing from too profuse a wetting. There being no air pressure on the surface of the solution in the earthenware cell, it can only percolate with extreme slowness, being opposed by the pressure of the air acting through the iron borings and the pores of the cell. The presence of carbonic acid in ordinary water renders it desirable to make the solution with distilled or newly-boiled water. If this is done, and the cell instantly closed with an air-tight stopper, the conditions necessary to secure the best results have been complied with. Instead of distilled or boiled, common water may be used if a portion of newly-slaked lime is added to the solution before closing the cell.

Now, as to cost. The tinned iron can be used without detriment. The tin, being strongly electropositive to iron, sets up a local action with the borings as soon as the solution reaches it, and, being small in quantity, is soon resolved into tin oxide without injury to the battery. The soldered joints of American preserve cans are but very little affected by the solution, and can be depended upon not to leak if tight in the first instance. The borings never need renewal, as they do not rust, and are not changed in any way by the action of the battery. The zinc may be of the commonest kind, as no local action of importance has been observed unless the caustic alkali used is very impure. Amalgamation is therefore useless. Strips of common roofing-zinc rolled into cylinders answer perfectly well. The porous cell is the most expensive item, but this can be dispensed with by the use of diaphragms of canvas, or other fabric of vegetable origin. It must be remembered that the caustic alkalis destroy all animal tissues, so leather, bladders, &c., are not admissible. The author has tried cells of thin wood, such as willow-boxes, with success; but the earthenware is more permanent, and, in spite of its prime cost, probably the most satisfactory in the end. Such as the one before you can be procured wholesale at 2d. each. A diaphragm of some kind is absolutely necessary. Caustic soda, in a state of reasonable purity, is made in the neighbourhood of Glasgow, and can be obtained wholesale at a little over 1d. per lb. Whether this is sufficiently pure for long-continued action has, however, yet to be determined. To sum up the cost of one cell in its simplest form, we have can and borings $\frac{1}{4}$d.; porous cell 2d.; zinc, say 1d.; soda, 4oz. $\frac{1}{2}$d.; soldered wires for connections 1d.; labour $1\frac{1}{4}$d.; total, 6d., which is quite a liberal allowance.

The battery is, consequently, probably the cheapest ever devised, in proportion to its power and durability, when regarded in the light of prime cost, but it becomes even cheaper when it is considered that the chief product of its action is zinc oxide, known in the paint trade as zinc white, which is extensively used as a pigment and as a substitute for white-lead generally. It can easily be recovered in an approximately pure state from the used-up battery. From the cell which rang the bell for a month 1,458 grains, or 3·04oz. troy, were recovered, the zinc consumed being 1,170·7 grains, or 2·44oz. troy. Some of it—one sixth of the quantity recovered—is on the table before you

Its price in the market ranges from 6d. to 1s. 6d. per lb., according to purity. As this is by no means a bad sample, containing only a very slight trace of iron, its value exceeds that of the zinc consumed. I has been said that voltaic batteries can never compete with dynamo-machines, because the zinc used takes coal to reduce it from its ores to the metallic state, which coal would have produced the energy direct if burned in the furnace of a steam-engine driving a dynamo. But if the product of the consumption of zinc in a voltaic battery can be made to defray the cost of the zinc, that oft-quoted argument somewhat loses its force.

THE CAUSES OF COLLIERY EXPLOSIONS.

In the course of a lecture "On Colliery Explosions," delivered at Firth College, Sheffield, last Saturday, Prof. Carnelley introduced a number of experiments showing how colliery explosions are produced. Amongst the principal causes of explosions mentioned by the lecturer were insufficient ventilation, the result of which was that the fire-damp was not diluted to such an extent as to render it inexplosive; the sudden emission of gas by blowers; and the temptation which the poor light of the lamps afforded to the men to use naked lights. Since gunpowder and other explosive bodies had been used for removing coal by blasting, a very serious source of accident had been introduced, which had been the cause of a good number of fatal catastrophes. Accidents of this class arose in four ways: the carelessness with which gunpowder and other explosive bodies were handled and stored by the men; the direct ignition of the explosive gas by the flame from the shot; the concussion of the report dislodging fire-damp from the cavities in the roof and workings, and coming in contact with a naked flame or defective lamp, causing an explosion; and, fourthly, the discovery of Mr. Galloway, that explosions might be due to the sound-wave produced by a blown-out shot driving the flame through the gauze of the lamp, thus igniting any explosive mixture outside. This important discovery, which accounted for many terrible explosions, was thus illustrated by Dr. Carnelley: He took a zinc tube 15ft. long and 6in. internal diameter, and at one end suspended a lighted Davy-lamp, which, by an arrangement of gas-jets, he surrounded with an explosive atmosphere of gas and air. At the other end of the tube he placed a little glass bulb, containing a mixture of hydrogen and chlorine. On bringing near it a bright light, produced by burning magnesium, the hydrogen and chlorine united with great force, causing a loud explosion. The sound-wave passing along the tube drove the flame of the Davy-lamp through the gauze and ignited the gas outside, proving that sound-waves were capable of causing explosions in the way discovered by Mr. Galloway. Another important element in colliery explosions is coal-dust. A combustible body such as flour or coal-dust in a very fine state of division, and suspended in air, and especially if the atmosphere contained small quantities of explosive gas, is capable of forming an inflammable mixture, and of increasing considerably the force of an explosion of a mixture of fire-damp and air. When a single particle of such a substance is ignited, the ignition is communicated to the neighbouring particles with increasing rapidity, till at last an explosion results. Dr. Carnelley illustrated this statement by pouring some well-powdered coal-dust down the mouth of a glass vessel containing a mixture of of air and coal-gas. On applying a light a violent explosion took place, and at the same time the ignition of the particles of coal caused the globe to be filled with a number of luminous points. In this case Dr. Carnelley explained that the force of the explosion was considerably greater than the one produced by a mixture of air and coal-gas only. These facts showed how great explosions might occur in mines containing air and dry coal-dust with but little fire-damp. The force of the explosion, too, was much increased by the fact that a great part of the solid coal-dust, of small volume, became converted into gases occupying a volume very much larger. Looked at in the light of these facts, there was no doubt that the attempt recently made in some mines to screen the coal below ground was a most serious and dangerous mistake, as it would lead to a largely-increased diffusion of finely-divided coal-dust through the air of the mine. The action of coal-dust was chiefly of importance, and could only lead to explosions in dry mines. In damp mines no explosions had been traced to this cause; the most effectual preventive, therefore, was to keep the floor of the mine continually wet, either with water alone, or with a weak solution of calcium chloride. Many persons had denied that sudden changes of weather could have any effect upon the frequency of explosions in coal-mines, but this point had been apparently conclusively proved by Scott and Galloway, who had constructed a series of tables showing the connection between the number of explosions and sudden changes in the weather. Thus, for 1873 it was shown that 58 per cent. of the explosions were due to changes of pressure, 17 per cent. to heat of the weather, and 25 per cent. were not attributed to meteorological agencies. It was thus proved that fire-damp was more prevalent in mines with a low barometer and high temperature than under the reverse conditions. He illustrated this by means of an oblong box, divided into two unequal compartments by a plate of plaster of Paris. The smaller compartment was filled with coal-gas, which diffused slowly through the plaster partition (supposed to represent the face of the coal) into the other compartment, the further end of which was closed with a paper drum. The second compartment contained a burning candle, which at first burned quietly, because the gas only diffused very slowly through the plaster; but when the pressure in the compartment containing the candle was suddenly lowered, the gas passed more rapidly through the plaster division, and an explosion occurred. In a similar manner fire-damp issued more rapidly from the face of the coal in a mine when the atmospheric pressure suddenly fell. A sudden change of weather, especially a turn to the south-west, with low barometer and high temperature, would cause a great evolution of fire-damp from coal. It was, therefore, important that a constant watch should be kept over barometer and thermometer, and that only safety-lamps should be employed during an unsettled state of the weather. With a good ventilation, however, the above effect of weather might in most cases be eliminated.

ELEMENTARY LESSONS ON DRY PLATE PHOTOGRAPHY.*

Selection of Apparatus.

The first thing the beginner has to do, is to determine what size of "plate" he will work—that is to say, how large his pictures are to be. As a matter of course, he should begin work upon the smallest plates which he can buy, as the first few results are sure to be far from perfect, and the cheaper the plates spoiled the better. That does not, however, bind him to the smallest size. In considering size of plate to be worked, it must be borne in mind that the larger the plate the greater the weight to be carried into the field, the greater the difficulty of manipulation, and the heavier the expense at every turn. This being the case, we would suggest as a good size that known as "half plate"; that is a plate measuring $6\frac{1}{2}$in. by $4\frac{3}{4}$in., which allows of pictures being taken of the popular cabinet size, and the apparatus necessary can very easily be manipulated in the field. Having decided the size, the next thing to consider is in what manner to purchase the apparatus; and here we must say emphatically that the only way in which to be sure of getting reliable photographic requisites is to go to a first-rate dealer, and to purchase them new from him. There is a general idea in the mind of the non-photographic public, probably gained from seeing numbers of old cameras and lenses exposed for sale in pawn-shops and such like, that great bargains are to be made in second-hand photographic apparatus, and that the beginner may "pick up" what he wants very cheaply by a little looking about. There can be no greater mistake. The experienced photographer may occasionally pick up an article very cheap; but the man without technical knowledge will be sure, if he attempts to do the like, to find on his hands goods which will be useless to him when he has somewhat advanced in his art. The "sets" made up by most of the chief photographic dealers are most excellent and complete; but the sum charged for them is greater than many are willing to lay out at once. These may buy at first only those articles which are absolutely necessary to begin with, and may add to their store from time to time, as they think fit. We give a list of the articles most necessary for working quarter-plates, a camera, a lens, a tripod stand, three flat dishes or trays of porcelain or other material, a graduated measure, holding a $\frac{1}{4}$oz., a graduated measure holding 4oz., a dozen gelatine quarter-plates, a dark-room lamp.

A photographic camera is, as probably everyone knows, a sort of box, at one end of which is held the sensitive plate, and at the other end of which is held the "lens"—which latter throws an inverted image of any object in front of it on to the plate—and that there is a means of adjusting the distance between the lens and the plate, or of "focussing" the camera. Every camera has, besides this, a piece of ground glass, which can be put in the exact place to be afterwards occupied by the plate, and upon which the image can be seen so as to facilitate focussing. It is also fitted with a "dark-slide,"—a sort of case in which a sensitive plate may be fixed. After the camera has been focussed, the dark-slide is placed in the position before occupied by the ground glass, which latter is removable. The "shutter" or sliding-door of the dark-slide is then removed, and, on taking the cap off the lens, the image falls on the plate. As many dark-slides as are desired may accompany a camera, and thus a number of plates may be carried into the field. Slides are also constructed to hold two plates each, and are called "double dark-slides." These are by far the best and most convenient to use for dry plates. Three slides are a common number to accompany a camera. This enables half-a-dozen plates to be carried out. Each dark-slide should be fitted with a set of carriers. "These enable plates smaller than the largest size for which it is constructed to be placed in it."

All modern cameras for use in the field are made with bellows-bodies so that they can fold up into small compass for ease in carrying. In purchasing a camera, the photographer should get one which will open to a considerable distance—if possible, as much as twice the length of the largest size plate which it will work. In some part of his career the amateur is sure to aspire to the taking of portraits. His attempts in this direction are almost certain to be failures, and to cause great pain to his friends, but nothing is surer than that the portraiture fit will attack him. When it comes to this, he will find a camera which opens to a considerable length a great advantage.

There are various adjustments attached to modern cameras which, although of little use in the hands of the beginner, will be found of great convenience to him when he is more advanced. These are chiefly a vertical and horizontal adjustment of the front on to which the lens is screwed, and what is called a "swing-back." This latter provides a means of varying to a certain extent the angle between the sensitive plate and the axis of the lens. A leather case into which the camera and the dark-slides fit, should be provided. A "single achromatic" lens of such a length of focus as to enable the largest plate which the camera will hold to be covered should be purchased. The lens should be bought direct from some reputed maker. The particular form of lens known as the "wide-angle landscape" lens is the best. The tripod stand calls for little special remark. The only requirements of the camera stand are that it should be light, should be easy to fit up and take down, and should be quite rigid when fixed up. The flat dishes or trays—or, as they are sometimes called, flat baths—are for use in the operations of developing, fixing, &c. Such dishes, made of so-called porcelain, can be had for a few pence each, and we should reccommend that such be purchased for quarter-plate work. When the photographer advances to larger sizes, he may indulge in the more expensive and more convenient dishes made of ebonite and other light material.

SCIENTIFIC SOCIETIES.

SOCIETY OF ENGINEERS.

At a meeting of the Society of Engineers, held on Monday evening, the 6th instant, a paper was read entitled "Notes on Electric Light Engineering," by Mr. C. H. W. Biggs, and Mr. W. Worby Beaumont. The few fatal accidents which have attended the employment of powerful electric currents for lighting purposes were first touched upon, and it was shown that these were entirely due to insufficient care in insulation and need never recur. The calculation of resistances was next touched upon, especially with relation to the best arrangement of circuits and internal and external resistances of dynamo-machines, so as to secure the most economical results. The substitution of iron for conductors of large size, in place of copper, was next touched upon, in view of the possible rise in the cost of copper, when many miles of conductors of large size are required for large installations, iron being shown to be cheaper, though the weight required would be about as 2·7 to 1. The different sources of motive powers were considered, steam-engines being preferred as more economical, more uniform in velocity of rotation, more reliable, and as being capable of more precise regulation than gas engines as at present employed. Secondary batteries as accumulators and regulators were also referred to as having an important place in electric lighting and power transmitting plant, and descriptions were given of some forms of these as now before the public, which were published nearly twenty years ago. The cost of electric lighting on a large scale was given as about two-thirds that of gas.

The ports of Quebec and Montreal are nearer to Europe by 430 and 250 miles respectively, and nearer Chicago, the great central grain depot of the West, by 140 miles, than New York, and are better situated for the shipment of the products of the Western States.

SCIENTIFIC NEWS.

THE Rev. Thomas Romney Robinson, D.D., died on the last day of February in his 90th year. So long ago as 1815 he was appointed Astronomer-Royal in Ireland, and held the post for many years, pursuing the study of astronomy with enthusiasm, and publishing works on the science which have been translated into foreign languages. He retained his mental faculties up to the last, and a letter from his pen on the "endowment" question, which we printed on p. 82, Vol. XXXIII., remains as evidence of his love of science for its own sake.

Dr. J. Palisa, of the Imperial Observatory, Vienna, discovered another small planet on February 9th, the second he has found this year and the thirtieth of his list. It is No. 222. The two planets discovered this year have been observed at Paris; but they are very faint, one being equal in brightness to a star of the 12th mag.; while the other is only equal to a star of the 13th mag. Names have been given by Dr. Palisa to the four planets he discovered in 1880. No. 212, Feb. 6, has been named Medea; No. 216, April 10, Cleopatra; No. 218, Sept. 4, Bianca; and No. 219, Sept. 30, Thusnelda.

In a lecture on the storage of energy, which we print elsewhere, it will be seen that Professor Ayrton referred to the experimental tramcar driven by Faure batteries, and an electromotor. This vehicle has scarcely had fair-play, as it was not adapted to the rails, and moreover, was limited to the short piece of line leading to the company's yard at Leytonstone. The car which has been used in France weighs with its accumulators and electromotor about 5¼ tons, the battery being capable of yielding 25 horse-power for one hour. It ran at a speed of about seven miles an hour, starting and stopping being effected with great ease by means of a small switch.

Dr. Werner Siemens has published his lecture on fire-risks of electric lighting, which he says is a subject demanding closer attention than it has yet received. There are especial dangers attending the introduction of the light into collieries, and he suggests that it should be sent through the workings by reflectors or by means of luminous paint, the painted surfaces being charged at a central lamp, and distributed throughout the mine.

The Victoria Cross Gallery at the Crystal Palace has been fitted up by the Domestic Electric Lighting Co., with a suite of elegantly-furnished rooms, to give an idea of the effect of the electric light as applied to modern mansions. There are an entrance morning-room, a smoking-room, a dining-room, and a drawing-room and boudoir. The system of lighting used is based on that of Edison.

The installation of the electric light at the Mansion House will be one of the sights of London, as it is complete so far as it goes. A Crossley gas-engine drives three Bürgin machines (a fourth is kept in reserve), which supply current to six Crompton arc lights in the Egyptian Hall, and a number of Swan incandescent lamps, arranged in electroliers in the saloon. If a statement of the cost of installation and working is forthcoming, say at the end of three months, such an experiment will be of considerable value.

A trial boring for coal is being made at Snaith, near Goole, on the estate of Lord Beaumont. It is known that the coal-measures of the West Riding extend eastwards, but it is not known how far, and as it is considered unlikely that they lie beneath Lincolnshire in workable shape, considerable interest is taken in the boring at Snaith, which was commenced last year.

The experiment of throwing oil upon the waters carried out at Peterhead by Mr. Shields, of Perth, seems to have been successful, and to have borne out the statements of mariners. Crested waves, as soon as they reached the oil-covered portion, assumed the appearance of undulating waves, and presented an unbroken surface; but it is stated that the effect does not last so long as is desired.

The third lecture delivered by Prof. S. P. Thompson, at the Crystal Palace, was on electric arc lights. The electric arc was discovered about the year 1804 by Sir Humphry Davy, when experimenting upon the different kinds of sparks produced between wires of various materials attached to the terminals of a large voltaic battery. Pencils of hard artificially-prepared coke-carbon are now universally used instead of wood charcoal. To control the light the carbon pencils are held by an instrument called a regulator or electric lamp. The regulator has to perform the office of feeding the carbon pencils into the arc as fast as they burn away, the rate of feeding being controlled electrically by the strength of the current that passes through the lamp. Diagrams of the construction of the principal forms of lamp were shown, and several lamps of the various leading systems were exhibited in action. Illustrations were also given of the method of calculating the actual amount of energy used up in the lamp, as well as of its light as compared with that of a standard candle. The lecturer stated that the gas which would yield a horse-power of energy would burn with a steady light of 42 candle-power per hour, while the same amount of gas burned in a gas-engine and used to drive a dynamo-electric generator might maintain an electric arc light equal to that of 2,000 candles.

Vipers abound in some parts of France, more especially in Vendeé, Loire-Inférieure, Haute-Marne, Lot, and Côte d'Or. In Haute-Marne 57,045 were destroyed in six years (a premium of about 2d. having been offered on each animal). According to M. de Quatrefages, the larger domestic animals recover pretty quickly (without treatment) from a viper's bite; but goats, sheep, and dogs often succumb if not treated. A bitten man may recover spontaneously, after considerable suffering; but the issue is often fatal. In view of these facts, M. de Quatrefages has called attention to the treatment with permanganate of potash recently found successful by the Brazilian, Dr. de Lacerda. The doctor insists on the importance of preparing the solution only at the time it is required, and advises keeping small packets of about 1½ grain of the salt and a flask holding about ⅓oz. of water (0·1 gramme and 10gr.). The Pravaz syringe is used in injection; a ligature is placed above the bite, and the tissues are compressed to promote diffusion. The method is applicable to domestic animals as well as men. M. de Quatrefages throws out a suggestion that the permanganate might be effective against the diseases which M. Pasteur has recently done so much to elucidate.

The monks of Mount Athos, the "Holy Hill," have now the opportunity of telegraphic communication with Salonica, in the Turkish system. The mountain, it is known, is situated on a promontory, and rises more than 6,000ft. above the sea-level. The monasteries contain some 6,000 Greek monks of the Order of St. Basilius. They are seminaries of the Greek clergy, and are visited every year by thousands of pilgrims.

An extraordinary proposal made a few years ago by Prof. Shaler, of Harvard, has been lately revived and is being discussed in American papers. The climate of the northern portion of America has, during a few centuries, been growing colder, and this Prof. Shaler attributes to rise of the land at Behring's Straits, interrupting the warm Japanese current which penetrated the Arctic Ocean, and turning it towards California and Oregon. The upheaval has now ceased, and will probably be followed by subsidence, restoring the old state of things. Prof. Shaler proposes to hasten the result by clearing away three small islands in the narrowest part of Behring's Straits (which is thirty-six miles wide, with a depth of thirty or forty fathoms), as also some obstructing rocks and reefs along the shore. If civilised nations would unite in giving the money, men, and energy, they now devote to keeping themselves ready to fight each other, the thing might easily be done (Prof. Shaler thinks) and a vast empire reclaimed for civilisation.

The behaviour of so-called "compass plants" has been lately studied by Prof. Stahl. The common one is *Silphium laciniatum*, but Prof. Stahl has noticed in the case of *Lactuca scariola* also, that its leaves generally point in a north-south direction. The peculiar position of the leaves is best seen in bright sunlight. In *Lactuca*, the leaves on the north side of the stem become vertical by twisting of the leaf-stalk, the upper surface of the leaf facing the east. Those on the south side become vertical with the upper surface to the west. The leaves on the east and west become upright with their upper surfaces approximated to the stem. Leaves of plants exposed to direct sunlight only from 10 to 3 did not take the meridional position, but those exposed only before 10 and after 3 did. That this position is produced by the sun when near the horizon is clearly shown thus :—A pot with several young plants was placed in a window facing the north, getting direct sunlight a few hours after sunrise and before sunset. Here the leaves bent towards the north with their upper surfaces turning either east or west. The pot was then placed further back, beyond the reach of direct sunlight. The leaves then took a position at right angles to the diffuse light from the window. Prof. Stahl mentions three other plants in which a meridional position of the leaves may be clearly seen.

A new mode of lighting has been introduced in a lighthouse south of Macquarie Head, near Sydney (New South Wales). The apparatus is adapted for either gas or the electric light, the former being used in clear, the latter in dull and foggy weather. The gas is conveyed from Sydney, 2½ miles off, and the electricity is generated by one of De Meritens' machines. An arrangement of prisms has been contrived, through which a dioptric apparatus can be satisfactorily utilised with the electric light.

There were 7,177 applications for patents in Germany last year, and the number has been continuously increasing of late years (in 1878 it was 5982). The number of patents granted was 4339. This was exceeded in 1879 (4410). In the United States last year the number of patents was 13,947; and since 1860 no fewer than 200,000 patents have been granted.

To free bones and other substances of fatty matter, Herr Richter, of Breslau, first subjects them to vacuum, then admits a little benzine to saturate the bones, works the air-pump again, and after some time, admits air, so that the solvent returns from the vaporous to the liquid state, and the fat is dissolved. The fat solution having collected at the bottom of the vessel, the air-pump is again worked to vaporise the solvent.

The laying of a telegraph-cable through the St. Gothard Tunnel has been completed. The cable is about 1·4in. thick, and consists of seven independent lines.

In Germany there are 16 locomotive works which supply large locomotives for the normal lines. They deliver 1,600 to 1,900 locomotives in a year. Nine of them are in Prussia, three in Bavaria, and one each in Saxony, Baden, Wurtemburg, and Alsace-Lorraine. The largest works are those of Borsig, in Berlin, and of the Hanover Machine-making Company in Linden, Hanover, each delivering 200 to 250 locomotives a year. There are, further, four works which supply small locomotives almost exclusively (65 to 80 a year). Austria-Hungary has four locomotive works with a yearly delivery of 350 to 420 locomotives. Switzerland one (Winterthur), with a yearly delivery of 40 to 50.

Most deaf-mutes, it has been shown by M. Boucheron, have become deaf through affections of the ear, not through brain affections or malformation. He considers the deafness to be produced through compression of the acoustic nerve, the result of a vacuum occurring in the tympanic cavity, so that the tympanum is pressed in. The compression of the nerve results in degeneration, and, perhaps, destruction. Further, many young deaf mutes have difficulty in keeping their balance, frequent giddiness, &c., and M. Boucheron attributes this also to *otopiesis* (*i.e.*, ear-pressure), acting on the nerves of the semicircular canals of the ear, which are well known to be concerned in equilibration. On this theory, if the compression be relieved, the patient should benefit. M. Boucheron has verified this in several cases: he introduced a few bubbles of air into the tympanic cavity. Deaf-mute children that had been unable to walk, were enabled to walk normally, and both hearing and speech returned. Moreover, the tendency to times of excitement, utterance of hoarse cries, &c., often manifested by deaf-mutes, disappeared.

"HEDGING" IN SUNSPOTTERY—THE TRAPEZIUM OF θ^1 ORIONIS—AREA OF A SEGMENT OF A CIRCLE—PRIVATE MUNIFICENCE IN CONNECTION WITH REAL SCIENTIFIC WORK—AMATEUR OBSERVATIONS OF THE COMING TRANSIT OF VENUS—URANUS IN A 2 7-8in. TELESCOPE.

[19790.]—THERE is an operation in the sporting world familiarly known among betting men as "hedging," and I should like to invite especial attention to the artful way in which a cognate course of proceeding is being adopted by the gentlemen who believe (or make believe they believe) in Sunspottery. We have been told, over and over again, on the highest authority (among the Sunspot gentry), that increased solar activity, as manifested by the appearance of numerous spots, faculæ and prominences, is always accompanied by a marked and notable increase of terrestrial heat, and that the temperature in years of few sunspots is below the average. It is then rather amusing to find a Mr. Archibald writing in the official organ of the Sunspot party, that a table of certain Indian meteorological details "most decidedly favours the hypothesis Prof. Hill and myself have all along regarded as the best working hypothesis—viz., that the Sun radiates *most* heat to the earth in the years of *fewest* spots" (!) This is highly instructive. One famous Heliostigmatist—say Smith—asserts that increased solar activity means increased terrestrial heat; another, quite as famous—call him Jones—states with equal confidence that such increase of heat occurs coincidently with solar quiescence. Observe the use which can, and will, be made of the public expression of two such diametrically opposite opinions. Should the present year (in which, as is well known, we are close upon a maximum period) prove an abnormally dry and hot one; we shall have certain persons proclaiming it upon the house-tops with the addendum—"This affords a striking and most appreciable corroboration of the views so consistently maintained by Smith." On the other hand, should it turn out a particularly cold one, then will our attention be pointedly called to "the exact accordance between the observed meteorological conditions, and those following from the adoption of the theory of Jones." All this is irresistibly suggestive of the prophecy in the *Weather Almanack*, "It will be wet on the 27th, unless it is fine, in which case it will not rain." It is, however, rather difficult to imagine whom it is intended to delude by so very transparent an artifice as this.

Apropos of the Trapezium of θ^1 Orionis (letter 19760, Vol XXXIV. p. 592), it may not be without interest to note that while, at the beginning of the season I found the 5th Star by no means an easy object: it has apparently brightened considerably during the last few weeks. I am convinced that trustworthy photometrical observations would show this Star to be variable.

I have repeatedly said, in these columns, that I will not do sums. Inasmuch, however, as a full answer to query 46204 (Vol. XXXIV., p. 603) involves the exhibition of some rather interesting principles, I will reply to it somewhat in detail, even if such reply does involve a certain amount of calculation. The most obvious way of attaining the result sought by Mr. Pendrill is then evidently to find, in the first place, the area of his whole circle, and to deduct from this the area of the segment of the smaller arc of 114° 15′. We, therefore, begin with the circle. And here we say: rad.$^2 \times \pi =$ area—i.e., $24{\cdot}375^2$ft. × 3·1415927 = 1866·518 square feet, the area of the whole circle. Our next proceeding is to ascertain the area of the sector, whose angle is 114° 15′. This we do by the proportion 360° : 114° 15′ : : 1866·548 : (what we shall find to be) 592·3697ft. From the area of this sector, however, we must evidently subtract that of the triangle formed by the two radii and the chord of (equal to twice the sine of half) the arc. Assuming that, as a matter of course, your correspondent knows how to compute the area of this triangle, it may suffice to say here that it is 270·858 square feet. Then 592·3697 − 270·8580 = 321·5117, the area of the segment whose angle is 114° 15′. Finally, taking this from the area of the whole circle thus: 1866·548 − 321·512, we get 1545·036 square feet as the area of the segment whose arc contains 245° 45′ in a circle whose radius is 24ft. 4½in. This seems a very operose piece of work, but I know of no way of simplifying it for the purpose of practical calculation.

The first paragraph of your "Scientific News," on p. 610 of Vol. XXXIV., is both interesting and instructive, illustrating as it does the facility which exists for obtaining money for any absolutely defined and legitimate scientific purpose. Our American cousins have set us a noble example in this way; nor do British colonists seem much behind them in munificence, when they are assured on such unimpeachable authority as that of the Astronomer Royal at the Cape, that their money will be devoted to the real advancement of Astronomical knowledge. In curious contrast to this is the fact that a "Committee of Solar Physics" had to be secretly and surreptitiously established at Brompton, and subsidised from the National Exchequer for many months before the general public could hear one syllable of the matter. The reason for this, however, is not far to seek: the fact being that no Scientific man, competent to judge, could or would subscribe five shillings towards the sustenance of such a contemptible little sham; and so the money had to be got out of Government officials, who were in sublime ignorance of the purpose to which it was to be devoted. But for the way in which the "Solar Physics" juggle has been exposed, it is an insult to common-sense to believe that a subject of such (alleged) enormous importance would not long ago have been investigated at the cost of men to whose princely donations to science (anonymous and avowed) it owes so much of its recent rapid progress in this country. Once show Englishmen that "endowment" is intended to forward the study of legitimate science, and is not being artfully worked merely to obtain a genteel form of outdoor relief, and I will answer for my fellow countrymen that their money will be forthcoming as freely as that of any English-speaking race on either side of the Atlantic.

All that "E. J. B." (query 46229, Vol. XXX., p. 626), or anyone else, can do on the 6th of next December is to observe, with all conceivable accuracy, the instants of the external and internal contacts of Venus at the time of her entrance on to the Sun's disc. External contact, as my querist doubtless knows well, is the appulse of the planet's preceding limb to that of the Sun. Internal contact that of her following limb (after she has begun to cross the Solar disc) with the Solar limb. For such observations to possess any scientific value, it is imperatively necessary that your correspondent should, imprimis, possess a telescope of at least 4in. aperture; and, secondly, a clock beating seconds, rigidly regulated to Sidereal or local Mean Time. I assume of course, too, that his latitude and longitude are both accurately known. Any observations, however accurate, must be valueless until the discussion and reduction of those made at other stations, as it is by taking into account the difference of times at which Venus apparently enters on to the Sun's disc, as viewed from stations widely separated in longitude, that the parallax will be mainly determined. It will be only some 4 minutes to 2 on the afternoon of the 6th that external contact at ingress will occur, and the Sun sets at 3h. 50m., so that comparatively little of the Transit will be observable under at all favourable circumstances in this country.

Certainly "Aidris" (query 46257, p. 626, Vol. XXXIV.), can find Uranus easily with a 2⅞in. telescope. A power of 220 would raise quite a perceptible blue disc upon Uranus, rendering him instantly distinguishable from any fixed stars in his immediate neighbourhood. His diameter at present subtends an angle of 4″, and that of Saturn one of about 16″, so that the diameter of Uranus would seem to be only one-fourth that of Saturn, and his superficial area only one-sixteenth of that of the former planet.

A Fellow of the Royal Astronomical Society.

DOUBLE STARS—P XXIII. 100—β DELPHINI—TRAPEZIUM OF ORION.

[19791.]—REFERRING to Mr. Hunt's communication with regard to P XXIII. 100 (letter 19299, page 133), I may say that I have measured the close companion to A on four nights, twice with 18·5in., and twice with 15·5in. At the time of writing the article quoted by Mr. Hunt, I had only observed it once, and, it may be, rather underrated the difficulty of this pair in stating that it could possibly be seen with an 8in. aperture. I am inclined to think now that it would be too severe a test for such an instrument, unless in a very favoured locality, and under the best atmospheric conditions; but there is no doubt that any good 10in. or 12in. refractor will show it properly under suitable conditions. This star belongs to a distinct class of doubles, not found in "Mensuræ Micrometricæ" at all, for the detection of which a telescope of first-class defining power is indispensable. A poor, or only moderately good, instrument in this respect will fail, however large it may be, to discover or even measure the more difficult examples of this class of unequal and close pairs. My own catalogues will furnish a large number of discoveries of this kind, many of them much more difficult than OΣ 496. It is not improbable that these excessively unequal pairs may furnish a distinct order of binary systems. The mean of the four measures of AB gives 1·37″, and the magnitude of the smaller component 10·9. The other pair, CD, I have measured on six nights in 1880-81, giving for the distance 1·43″, the distance between the two pairs being by the same series of measures, 75·75″. The faint stars in the field have no special interest other than as tests for small apertures, as they have evidently no connection with the brighter members.

With regard to β Delphini, M. Gaudibert (letter 19280, page 112) could not have seen the real elongation in the direction of 45°. During the past season, I measured this pair on five nights, the mean giving a positive angle of 14·92°. It is still a very difficult object, much more difficult now than I supposed when measuring it in 1880 it would be. The indications are, that it will be materially easier when available during the present season. An increase of one-tenth of a second in the distance will make it comparatively easy of measurement. It is hardly necessary to say that γ Andromedæ is now a very easy pair compared with this, and that the distance is much larger than the present distance of β Delphini. The last series of measures give the distance 0·26″, and I am certain these figures are not larger than the real distance. A correspondent of the *Astronomical Register* for June, 1881, in giving the provisional elements of the orbit, erroneously applied a correction of 180° to my angles of 1879, probably based upon the fact of my having noted the star as single in 1878. It must be borne in mind that although examined a good many times during that year with the 18·5in., there were only two nights when it seemed worth while recording the negative results, and then a distance of something less than 0·2″ might easily have escaped notice, as the seeing at the time was not the best; and it by no means follows because no certain elongation could be detected at that time, that an occultation really occurred between 1876 and 1879. In fact, the subsequent measures show this could not have happened, though the distance was probably less than at any time since the close pair was discovered. There never need be any uncertainty about the quadrant in measuring this with a suitable aperture, as there is a decided difference in magnitude between the components. I trust we shall soon have sufficient data for, at least, an approximate orbit of this very rapid binary system.

Mr. Sadler's history of the alleged discoveries in the trapezium of Orion will be read with interest by all who are familiar with this stellar group. Whether or not it may be worth while for observers, who have already looked for these supposed stars, to waste any more time in that direction may be an open question; but it certainly was the duty of the astronomers who claim to have seen what larger and better instruments utterly fail to show, to follow up these stars, if they had any faith in their existence, and measure their distances and angles, instead of leaving that entirely a matter of guesswork. The announcement of these discoveries by that method of proceeding would have been either deferred a week or two or postponed altogether. The corroborating evidence by several observers in favour of the existence of these stars should receive little or no weight, when it is remembered that nearly all the discoveries of purely imaginary stars, from the first down to Polaris and ε Lyræ, have been confirmed in the most unqualified way by subsequent observers. Unfortunately, these observers at this point drop out of sight, and nothing more is heard, so far as new observations and measures are concerned, of things so easily seen at the outset.

Chicago, February 22. **S. W. Burnham.**

TO MR. BRASHEAR.

[19792.]—WE are very much obliged to Mr. Brashear for his very interesting letter on plane-making; some points are especially interesting.

I edge my planes by screwing a plate of sheet-iron, well baked to make it tough and soft, on a long cast-iron bar, L-shaped, into the tool-holder of a slide-rest lathe, bending the iron over to suit the position of plane to be ground. The lathe is run at a quick speed, and fed with fine emery and water. In the absence of the slide-rest, the iron plate can be fixed to a joint on bed of lathe, and raised by a screw from underneath; but the slide-rest is by far the best. **G. Calver.**

WEBB'S MAP OF THE MOON.

[19793.]—Your astronomical readers will be gratified to learn that Messrs. Longmans have at last determined to confer a great boon on them by publishing, separately, the map of the moon, in Webb's "Celestial Objects."

More Light.

CLIMATE FOR ASTRONOMICAL OBSERVATION.

[19794.]—The Rev. J. J. M. Perry, in his letter 19680, p. 516, asked your correspondents to give him particulars of the nights on which observations could be made that he might compare them with his own.

I cannot give them for the year, but the last three months may afford him a comparison during the same period. My notes are as follows:—

December.—Nine clear nights, two partially clear, and twenty overcast.

January.—Nine clear nights, two partially clear, and twenty overcast.

February.—Nine clear nights, three partially clear, and sixteen overcast.

I cannot speak very positively as to the condition of the air on the nights on which I opened the telescope. December was, on the whole, fair, with one or two good nights. The same applies to January, with one bad night. In February, I have two fair and one bad night.

Fordingbridge. **T. Westlake.**

OBJECT-GLASSES AND EYEPIECES—TO "ORDERIC VITAL" AND OTHERS.

[19795.]—Those who are able to follow the contributions of "Orderic Vital," and others of your optical correspondents, will doubtless appreciate to the full their value as mathematical investigations, while even to others they will be found to contain many practical hints. May I, then, ask for certain particulars which are only indirectly touched upon, but which will I think prove useful to many of us if put into a simple form. Let us take an achromatic object-glass of, say, 5ft. focus and 4in. diameter, and combine with it an eyepiece of 1in. focus. Then, when adjusted for astronomical observation, we measure in the usual way the light-spot at eyepiece and find it (as the telescope would magnify 60 times) to be 4-60th in. = 1-15th in. diameter. But as a lens of an inch focus magnifies (at a standard distance of 10in.) ten times, it would follow that the o.g. alone would magnify six times, and that therefore the diameter of the light-spot at focus when the eyepiece is removed would be 4-6in. = $\frac{2}{3}$in. If tried, however, the size of light-spot differs considerably from such determination. What, then, determines the diameter of the focal light-spot in any given object-glass? Next, as regards eyepieces. The usual form of the Huyghenian is that with two plano-convex lenses; but if it were desired to employ two crossed lenses, of which the radii are as 6 to 1, how should the radii be determined in order that the combination may have any desired focus? Also, would the chromatic or spherical aberrations be increased or diminished as compared with the ordinary form. Lastly, if a single lens be used for an eyepiece, would it be advantageous to use a periscopic lens instead of a bi-convex or bi-concave; and, if so, what proportion should the radii bear to one another to obtain the best effect? Also, how can the radii be determined to procure a lens of any required focus.

I should, perhaps, also remark that in testing the focus of a lens or eyepiece, we use parallel rays, whereas, when used in a telescope, the rays that fall on it from the object-glass are convergent, and it would thus seem that to divide the focal length of the one by the other should only give an approximation to the truth.

Certain other considerations, which are of more difficulty, I must let stand over, or my letter will be too long. **Lens.**

TRICYCLES—SCREW-PROPELLERS.

[19796.]—No, "Sunlight"; I have tried sundry dodges anent sloping the seat at will, but didn't find them answer. I used to have the seat slightly tilted forward, like the driving-seat of a coach, and found it work very well; but a moving seat is uncomfortable and shaky. The fear of the Salvo type of machine tilting back is purely imaginary. As I have said before, the balance of the weight is a mere matter of adjustment, and as much or as little weight can be put on the steerer as the owner thinks fit.

Could not "White Swallow" give us a sketch, or at least, a rather more lucid exposition, of his new propeller? The more he describes it, the more he puzzles the reader to make him out. His paddles, or whatever they are, revolve, and describe a circle half in and half out of the water, entering and leaving the water perpendicularly. What can it be but a feathering paddle-wheel? And yet it isn't, but has direct thrust. Our curiosity is whetted, and not gratified. **Treadle.**

SCREW-PROPELLERS.

[19797.]—The discussion on the above subject has, very naturally, drifted from an inclined propeller fitted to a twin-boat, to ordinary screw-propellers fitted to sea-going ships. The subject is a very interesting one, and if any of your readers can so improve the efficiency of the screw or other propeller as to get a quarter of a knot an hour more than at present, they will find those interested neither confined to a certain groove, nor so wedded to the screw as to think that its principle cannot be bettered.

The late Mr. Froude found that the ship received in propulsive effect, by means of the screw propeller, only about 30 to 35 per cent. of the engine-power exerted. Let us, therefore, examine some of the sources of loss.

The water, following a vessel in motion, is found to do so at varying velocities. At the water-line, close behind the rudder, it generally travels as fast as the ship, and at the level of the keel it does not follow the vessel at all. The intermediate heights between these two extremes vary between zero and the speed of the vessel. But these currents are not horizontal, for they are partially broken up by the currents rising upwards under the buttock lines of the ship.

The water following the ship, at or near the water-line, cannot be interfered with without loss. The screw, however, in its usual place, acts forcibly upon all these currents: it breaks up and interferes, detrimentally, with the following water at the water-line, and it acts beneficially on the lower currents. The intermediate currents are not at all economically dealt with. If I treat the propeller blades as revolving as the hands of a clock, I may say at 12 o'clock it is absolutely doing mischief, and is quite in the way; at 3 o'clock it may be meeting the upward rush of water edgwise to the blade; at 6 o'clock it is doing its best, and at 9 o'clock it may receive the upward rush of water on the back of the blade, and thereby receive as much backward thrust from the water as it is able to obtain upon its driving face. This is the reason why propellers are much more efficient when placed further aft, and not in the conflicting currents.

Now, if the above reasoning is sound, it follows as a matter of course, that a simple sculling action would be more efficient than the screw. The scull should not be vertical,, but *square to the buttock lines*. The fulcrum of the scull should be near the water line; conveniently above it for renewal or repair, while at sea, and, of course, at the stern. The scull should oscillate through a distance of from 60° to 90°. The effect would be that the driving face of the blade would act very nearly in accordance with the varying currents mentioned above. The least effect would be at the surface, as it would be near the fulcrum, and the greatest at its outer end: in fact it should be designed to suit the shape of the vessel.

In case of the scull breaking in a heavy sea, it could be unshipped and another fitted in its place, and there would be no stuffing-box under water to give trouble, as with the screw. In case of the rudder being disabled, the scull can be used for steering, by stopping the engine for a few seconds when the scull is at port or starboard, and also if the ship is under sail only.

I have given a great deal of thought to the palpable defects of the screw-propeller, and also to the efficiency of sculling as a probable future propeller for steam-vessels, and I think the scull deserves a full trial. **Thomas Moy,**

37, Farringdon-street, March 3.

ON THE PRODUCTION OF CURVED FORMS BY MEANS OF A LINK ATTACHMENT TO THE SLIDE-REST.

[19798.]—When it is required to produce a surface of irregular or varying curvature, a template cut to the desired form is the means generally employed; but when a surface of regular curvature is needed, there seems no practical reason, why the motion of the cutting-tool, should not be controlled by a link attachment to the slide-rest.

It is not difficult to devise an arrangement of three bars, which shall give a circular motion. I remember reading a description of such an apparatus, which I think was called Anderson's circular attachment. But three bars can also be made to give an elliptical motion. Take two slotted bars A D and B C of equal length, and pivot them at the extremities, C, D, of a shorter bar C D. In a plate, attached to the under side of the longitudinal slide, fasten two steel studs, A and B, at a known distance apart, having extremities which will move easily but accurately in the slots of the bars. A suitable bolt, with a clamping nut, must be passed through the intersection of the bars, and its lower extremity turn in a hole in a rigid piece, which lengthens the tool-box slide. By means of the nut E clamp the bars at any angle A E B: then the simultaneous movement of the carriage on the long slide, and of the slotted bars about the fixed studs A, B, will cause the cutting point to describe the arc of a circle, of the same radius as that which passes through the three points A, E, B. To find the radius of this circle, or to fix the apparatus to describe a given radius, move it until the point E is equally distant from the centres of the studs A B. To find the radius described, carefully measure the distance apart of the centres of the studs A B; call half this distance b. Next, measure one of the distances A E or E B, and call this a; then, if r be the radius, it is given by the formula, $r = a^2 / 2 \sqrt{a^2 - b^2}$. Or, if it be required to set the bars to a given radius, we have, $a = \sqrt{2r(r \pm \sqrt{r^2 - b^2})}$. And the point E, that is, the centre of the bolt, must be at this distance from each of the points A B.

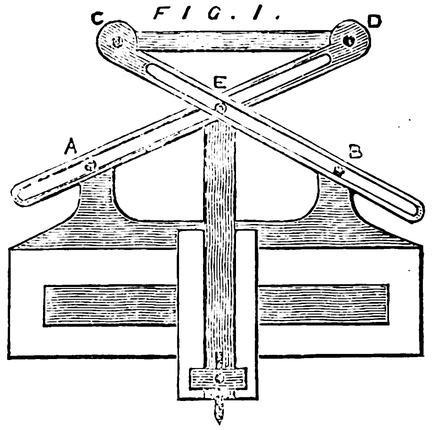

FIG. 1.

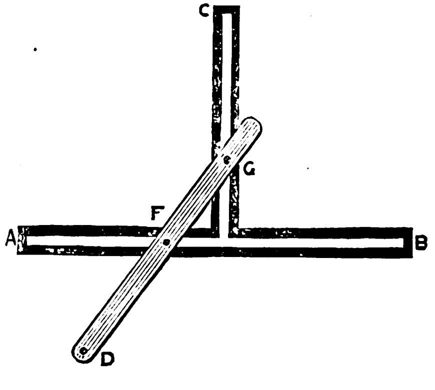
By a slight alteration, the same apparatus will give an elliptical motion. Instead of the bars being free to move about the fixed points, pivot them at the points A and B, and release the clamping-nut E. Then, if the bolt be free to follow the point of intersection of the bars, when they are moved about A B as fixed, and C D as movable, centres, it will describe an elliptical curve, whose major axis is A D or B C, and the distance between the foci A B or C D.

There is another way of describing an ellipse, which is perhaps more convenient than the above. Take a T square A B C, having channels or slots cut down each arm. D E is a movable lever, into which two pins F and G are inserted. When the pins are made to move, one in the vertical and the other in the horizontal channel, the extremity D will describe a portion of an ellipse.

In the position shown in the figure, it will describe the flatter portion of the ellipse; but if the bar be reversed, so that F moves vertically and G horizontally, the more curved part will be traced. The proportions of the ellipse will depend upon the adjustment of the pins F and G with regard to the extremity D. D F is half the shorter axis, and D G half the longer or transverse axis.

I am not aware that the parabola and hyperbola can be traced by any simple arrangement of levers similar to the above. Perhaps someone will tell us whether the usual lever and string movement can be obtained in any other simple way.

FIG. 2.



Apart from the consideration of this subject with regard to the lathe, can any of our practical opticians tell us whether any of the above or simila devices could be utilised in the production of lenses or specula? If a small polisher had its motion controlled by an apparatus similar to Fig. 2, of course, properly arranged, would not its *pressure*, and therefore its effect, be so regulated as to tend to the production of an elliptical surface?

With regard to Mr. Brashear's interesting letter, could not he persuade Dr. Hastings to contribute to these pages? He is, I presume, an amateur; and one of the very few who can use theory as a guide to practice. After the clever performance that Mr. Brashear speaks of, a few letters from such a master would be highly valuable to a large circle of readers. **Orderic Vital.**

DYNAMO-ELECTRIC GENERATORS.

[19799.]—"Quæstor" (letter 19773), implores someone to come forward to keep up the interest on this subject; therefore, though I may not be able to say much of value, I will contribute my little bit.

I cannot understand why it should subside just when one would expect it to be at its maximum. Mr. Caplatzi alone offers to give us an article, and I hope he will do so.

I have been studying and experimenting on the principles of dynamic generators for some time past, and it occurs to me very forcibly, in reviewing the present machines, that inventors have only troubled to produce something *different* from other machines, without inquiring whether their idea was *better* than those of others. Truly some have improved the very imperfect forms already existing; but it is impossible to make a perfect machine of one which is founded on erroneous principles, however it may be improved. Surely it were wiser to rake out the defects of the present machines, and then to devise one in which the said defects (or most of them) shall not exist.

In the Brush machine the armature is in the worst position to utilise the inductive power of the field-magnets, and it is impossible to place it in a better one, owing to the peculiarity of its construction. Also in all Brush machines I have examined, the various pairs of bobbins in revolving do not approach or recede from the poles of the field-magnets during more than a quarter of the revolution, and consequently it is only during this space that they contribute anything to the current. All the annular armature machines have this defect. Lastly, there is the great heating occasioned by the rapid reversions of the magnetism in the iron of the armature.

I have designed a machine in which all the defects I have mentioned, and one or two more are eliminated, and, the editor being willing, I shall be happy to send a brief description and diagram of it. **Conrad.**

[Please send.—Ed.]

MEDICAL REPLIES.

[19800.]—Troublesome Throat and Teasing Cough (46243).—I have seen scores of such cases permanently relieved by excising about a quarter of an inch from the end of the uvula. Of course this operation should not be performed without skilled opinion as to the case being really one to be benefited by it.

Rheumatism (46249).—If the daughter's joints or heart are not injured by the rheumatic fevers she may get quite well. To do that she should live in a dry, genial place, clothe herself carefully with flannel, live largely upon vegetable food, take regular exercise, avoid beer, wine and spirits, go to bed early. Of course she must avoid hot and crowded rooms, and attend in all points to the re-establishment of her general health, and the avoidance of causes which produce chill.

Enlarged Tonsils (46281).—If the enlargement is considerable a portion of it should be excised. Enlargement of the tonsils generally deteriorates the voice, but singing does not make the enlarged tonsil worse, unless it leads to getting the system poisoned by the bad air of crowded concert-rooms.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

WATCHES.

[19801.]—Would you kindly insert following queries? I think they will be of interest to many English mechanics, who like to have a good watch.

What is the difference between a pocket chronometer and an ordinary watch of good quality? Does the difference simply consist in the former being isochronised and adjusted for temperature and positions, or is there some specific difference in construction, as, *e.g.*, the chronometer escapement and cylindrical hair-spring?

What is the average rate of a pocket chronometer—*i.e.*, supposing it to go with perfect regularity, how much would it deviate from true time in, say, a week?

I understand such watches have no regulator, and therefore must be allowed to go as set by maker.

What would be its greatest probable variation from above rate in, say, a day? It is supposed to be treated in the most favourable manner—*i.e.*, it is kept perfectly stationary, and as nearly as possible at a uniform temperature.

What would be the effect of wearing it, and treating it as watches usually are treated—*i.e.*, with ordinary care, but with no extraordinary precaution?

Answer with reference to a good "English lever."

Are pocket chronometers made with a going barrel instead of a fusee, and if so, will they compare with these having a fusee?

Kindly give some idea (not an account) of the principles adopted in isochronising and adjusting for temperature and positions.

I am induced to ask the above questions because I hear so much of what I consider nonsense talked by watch-owners; and I should like to know definitely what an ordinary watch of good quality might be expected to do, and also what can be done by one of the very best. **Watch-Man.**

CONTINUOUS BRAKES.

[19802.]—"A Driver" (letter 19788) will find an answer in my reply to 46261, which appears elsewhere. I should be glad to know the action of the Gresham brake, said to be the best in late trials, but contradicted by the Derby officials as a mistake of the printer.

Enderby. **W. B. Holbech.**

A CHEAP AND EFFICIENT DOUBLE DARK SLIDE.

[19803.]—Doubtless there are many readers of the English Mechanic possessing cameras who would like to increase their stock of dark slides, but are debarred from doing so on account of the cost entailed in their purchase—the price of a double back ranging from 15s. to 50s. each. Seeing several queries of late upon the subject, I have been induced to send a description of a double dark slide I have recently made to take 7¼ × 4½ plates, at a cost of less than 6d. each.

I am indebted to a writer in one of the photo. almanacs for the design. The wood I used consists of the thin boards placed as a backing to pictures. They are about 4ft. 6in. long by 11in. wide, and 3-32in. thick, and should be procured as free from knots as possible. I gave 3d. each for mine. They will have to be sandpapered until a smooth surface is obtained. Cut two pieces the size the slide is intended to be to fit the camera, and out of these two pieces cut openings slightly smaller than the size of plate used, say, ⅛in. each way (A). Glue three strips of wood on the face of one of these pieces round three of its sides (B, Fig. 1), and then fasten another of the pieces of wood, with the opening, over all; this will be the groove for the shutter to work in. Four more strips of wood are now to be glued on to the face of this last piece, forming a rebate to contain the sensitive plate (C, Fig. 2), it should be slightly larger each way than the plate. This will complete one-half of the double back; the other is made in exactly the same manner, and the two halves are neatly hinged together.

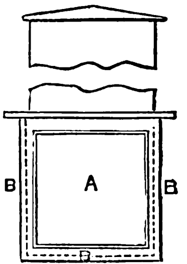


FIG. 1.

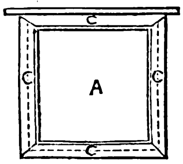
FIG. 3.

FIG. 2.



The top consists of a piece of wood about ¼in. thick, slightly longer than the body of the slide. It has two slits cut down its length for the shutters to pass through, Fig. 3, and care must be taken in fixing the top that these slits correspond with the openings in the slide. I have screwed this top piece on to one half of the slide, leaving the other half free to open. When the plates are in position the two halves are kept together by closing them and inserting the shutters.

I use the same wood for the shutters, and give it an extra sand-papering to make it work easily in the grooves. Two narrow strips of wood are glued each side of the top of the shutter, which is made to project above the top rail. The parts which enter the camera, as also the inner face of the shutters, should be stained black, and some opaque material interposed between the sensitive plates.

Care should be taken that the plates occupy the same position as the focussing screen. This should be accurately measured from the front of the camera. With regard to tools, I find a penknife answer every purpose, and in cutting the wood something should be used as a guide to the knife. The most difficult and tedious operation is cutting the slits in the top rail for the shutters. A small circular saw would be invaluable for this work.

I trust I have made my description clear, and should anyone feel inclined to make a dark slide, and be in doubt upon any point, I shall be pleased to help them through the query columns.

I have given few dimensions, as these must necessarily vary in each individual case.

J. B. Stephen.

PLANING AND MILLING ATTACHMENT TO LATHE.

[19804.]—With regard to what Fred Carre says, letter 19749, about not having a vertical feed on my milling arrangement, I never found the want of it, or I would have contrived one. The work can be set to any height by means of the vertical slots in the angle chuck, and the horizontal traversing motion and feed is all that is required for slot-drilling, with a proper-sized drill. And such work as drilling the recess for the screw of an eccentric chuck, or the radial slots in an ellipse or dome-chuck, could not be done under the planer head, as you could not commence the cut with a planing-tool close to the end of the slot, as the heel of the tool would be in the way. Of course, in drilling slots, it is necessary to have a couple of fluting-stops on the slide-rest. With respect also to what Fred Carre states about the strain being unduly severe in planing on the bottom slide of rest, I never found it so, and practice is better than theory. My metal-turning slide-rest is very massive, and the traversing screw is a square-threaded one, ¾in. diameter. Of course I have a separate slide-rest fitted for ornamental turning, as no one could use one which had done much heavy work for such a purpose—an ornamental rest requiring to be absolutely free from backlash in its screws. Also regarding what he says about the small range of thickness which can be admitted under the planer head: he must recollect that I had it made for amateurs' use, and not for a jobbing engineer's shop, and mine takes in a range of thickness of 7½in., which I have found quite sufficient for my wants. **F. W. G.**

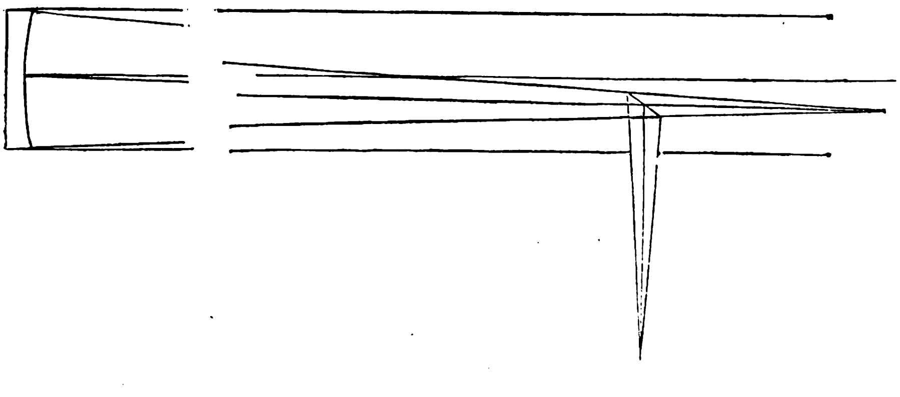
ADJUSTMENT OF MIRRORS.

[19805.]—I have read with much interest the valuable communications of Mr. Skelton, and of Mr. Westlake, on the refinement of the adjustments of reflecting telescopes, and as, in my opinion, there still remains an outstanding uncorrected imperfection in these adjustments, I wish to draw the attention of those gentlemen to this source of error, in the hope that they and the many other interested readers of the "E. M." may ponder on, and at length overcome, all the difficulties in the attainment of absolutely perfect adjustment.

It is my purpose to show that all the perfection of concentricity of mirror and flat, together with reflection of flat, and also the condition of perpendicularity of eyepiece with axis of tube, may exist, and yet the instrument be glaringly out of gear; but to render this clear I shall have to resort to a figure.

Let us suppose the mirror tilted in its cell, so that the focus will not coincide with the axis of the tube; let us place the flat so as to intercept the rays from the mirror, but on one side of the axis of tube. Now, by the usual adjustments, with all the refinement of the methods recently suggested, the flat mirror and reflection of flat can be adjusted into concentric circles with the e.p. tube, the flat being still in a line with the e.p. tube; there is nothing in this condition of reflection, however, to indicate that the flat is, or is not, in the centre of tube, nor that the mirror lies in its cell in such a manner that the axial ray will or will not return on itself; in other words, the focus of mirror will or will not fall in the axis of the tube. In short, the only difference which the condition indicated in the diagram will show on trial by the usual method is, that the flat, instead of appearing as a circle, will appear as an ellipse, either elongated in the direction of the axis of the tube or laterally, as the flat may be situated on the further or nearer side of the axis, the angle of incidence of the central ray on flat being either less or greater than a right angle; yet this difference in the appearance of flat, as viewed from the adjusting piece, will not be great enough to impress the observer, and consequently could not be readily detected. I do not deem it necessary to occupy valuable space to prove the possibility of concentricity of circles projected by mirror, flat, reflection, and inner end of e.p. tube. It can be proved both geometrically and experimentally. Of course, the irregularity in the adjustments above referred to, and indicated in the diagram, are such as deviate from the axial line only in the line of the eye-tube; a deviation laterally would be at once detected by ordinary means.

It is evident, therefore, that complete adjustment cannot be attained by merely securing extreme accuracy in the relative positions of e.p. flat and m. only to effect concentricity of reflections, and that it is essential to devise a method of ascertaining whether the focus of mirror lies in the axis of tube, no method that I am aware of having been devised that can at all compare with the ingenuity of methods devised to attain accuracy in the other adjustmentst. The one adjustment having been perfected, it is an easier matter to make the other adjustments. I therefore insist that it is of the first importance to know that the mirror is so placed that the axial ray will fall perpendicularly on the mirror, and am confident that an exact accomplishment of this will remove more than one half of the difficulties in the way of obtaining the best possible definition. An error introduced in this first setting must be transmitted through all the adjustments, and no degree of refinement and perfection lavished on the flat and central spot can remove the first error. The only method of ascertaining the position of mirror with regard to the axis of tube that I know of is to remove e.p. and observe the reflection of the end of telescope-tube, viewing the projection not from the centre of opening of e.p. tube, but by running the eye around the sides of the opening, and thus observing whether the tube projects equally all round. However, this is at best only a crude, indelicate test, and is, moreover, effected by the position of the flat as the projection is after all viewed from the flat. A slight change in the position of flat will cause a larger projection of the tube on one than on the other side.



I hope that some of your working correspondents will devote a little of their time to this subject, and work out a way to adjust the mirror to the axis of the telescope equally as perfect as the methods of adjustment of other parts of the instrument.

Wm. A. Haren.

St. Louis, Missouri, U.S.A.

ORNAMENTAL TURNING.

[19806.]—The thanks of all lovers of the lathe are due to Mr. J. H. Evans, for his kindness in communicating so much valuable information to our journal; and his willingness to do what he does so ably causes one to be somewhat reluctant to criticise adversely anything which he offers for our consideration. I hope, therefore, he will consider that I write in no unfriendly spirit when I plead generally for the production in ornamental turning of more artistic excellency of design than we usually see, and at the same time make some special reference to his design on page 605. With regard to this, and other similar designs which have from time to time appeared in our pages, I would remark that one looks in vain for simplicity and beauty of outline, as well as for artistic arrangement of the details of ornamentation. The circular form being the one naturally and most easily produced in the lathe, the turner is apt to fall back upon the circle as his chief item of ornamentation, and hence we find, in the general run of ornamental lathe-work, such a wearying repetition of circles and segments of circles. Nature (the imitation of which constitutes the perfection of art) rarely exhibits to us a circle or a circular curve, but generally parabolas, ovals, &c.; and in all good designs the circle, although sometimes freely used, is kept in due subordination to other forms. To do this in ornamental lathe-work requires no little amount of skill, and can only be accomplished by those who possess an artistic eye as well as a skilful hand. The specimen of work figured on page 605 shows a total absence of unity of design, and is composed of several pieces placed one on the top of the other, apparently without any definite purpose. The central stem also appears to be far too slender to support that which is placed upon it. I do not say that it "is" too slender, but that it "appears" to be so, which in the present case is the chief consideration, as the specimen is intended to be put under a glass case, and to serve merely as an ornament. It is necessary, therefore, that the design should satisfy the *eye*, which (in my case at least) it entirely fails to do. With regard to the details of ornamentation, these consist almost entirely of circles and segments of circles, which are themselves suggestive of circles.

An examination of the sketch of Mr. Coulson's vase on page 208, Vol. XXXIV., will show how beauty of outline is combined with ornamentation, the various details of which are in perfect harmony with each other; the circle especially, though freely used, not being allowed to appear too conspicuously. The outline of the vase consists chiefly of a beautiful flowing curve, no part of which can be said to be circular. The leading feature in the design is the large ellipse (of which there are four), and which is darker in colour than the inner ellipse and circle, though not shown so in the woodcut. The innner ellipse, consisting of the space between the two fine lines, is inlaid with wood set grain-on-end, giving a rich appearance to the work not shown in the engraving. This ellipse is not concentric with the outer one, but is placed rather higher up, thus giving "character" to the design. The inner-circle is not quite so dark as in the engraving, and is kept in due subordination by the outer ellipse. The small interior circles are interlaced in forms suggestive of triangles and squares, thus preventing the eye from dwelling too exclusively on the circular form. The same end is accomplished in the case of the circles round the neck, by their being connected together by narrow horizontal bands. This part of the work is inlaid with rosewood and boxwood. The small circles in other parts of the work are neither so large or so numerous as to interfere with the general harmony of the design, to which they contribute their share, but nothing more. The vase, viewed as a whole, may be said to be as faultless in design as it certainly is in workmanship; and to the combination of these excellences Mr. Coulson doubtless owes his success as winner of the first prize. The engraving only gives, as might be expected, a poor idea of the vase, photographs of which can be obtained by application to Mr. Clark, photographer, Thirsk.

A Country Parson.

[19807.] In again thanking Mr. Holtzapffel, I need only to mention the data which are still wanting in order to enable his clients to use their screws intelligently, and to understand the boring out and screwing of their lathe-chucks. For this I offer no apology, as Mr. Holtzapffel has already assured us that his firm never make an enigma of anything, and that he would willingly answer my questions. Moreover, as we all know, not only does Mr. Holtzapffel really mean what he says, but he is always prepared to assist in diffusing scientific knowledge upon the use of the lathe.

1. No diameters for the screws at bottom of thread have been stated. Without these diameters we have no means of sizing the drills, by which the holes to be tapped should be bored out. Skilled mechanics may instinctively allow for the depth of the threads, but amateurs, who work rather by trained brains than by trained fingers, need to see in their screw-threads an intelligible and coherent system. Do the Holtzapffel gauges define this second set of diameters?

2. In using the shallow-thread screw-tools (60° instead of 50°) some third set of diameters must be arrived at either by the holes to be tapped being drilled larger or by the finished screws being made smaller. Do the Holtzapffel gauges define this third set of diameters? If not, should we drill the holes larger inside or make the screws smaller outside?

3. Are two sets of the alphabet tools kept in stock, one for the deep threads and one for the shallow threads? If, as I rather gather, alphabet tools of the shallow thread are not kept and the shallow thread is only used *exceptionally*, one would like to know more precisely *when* this thread should be used. I understand that with certain materials we should use the shallow-thread tools, and that, in such case, we ought properly to bore out our chuck with a drill rather larger than the ordinary lathe-bit.

4. Holtzapffel's Catalogue and Vol. IV. shows that five mandrels are issued: *i.e.*, the 4, 5, 6, and 7in. centres for ordinary lathes, and a 6in. centre-mandrel with "truncated angular-screw," for the screw-cutting lathe. In the latter, Mr. Charles Holtzapffel's programme for aliquot threads has already been adopted; but the mandrel-noses otherwise appear to be rated by the numbered screw-tools, and to be sized by a special set of gauges. May we have the screw-threads and the sizes, top and bottom of thread, for the Holtzapffel mandrels so that we may understand how to choose a lathe-head, and know how to size the drills for boring out our lathe-chucks?

Once more I cordially thank Mr. Holtzapffel on the part of the readers of the English Mechanic. I am sure that Mr. Holtzapffel will rejoice to see a spirit of inquiry arising as to ornamental lathe questions, and that he has no wish to abdicate the leadership in matters on which further scientific developments are to come.

James Edmunds, M.D.

Grafton-street, Bond-street.

COMBINED ECCENTRIC CUTTER AND DRILLING INSTRUMENT.

[19808.]—Anyone who has done any ornamental work in the lathe, in which he has had occasion to use both the eccentric cutter and drilling instrument for different parts of the same work, must have experienced the nuisance of having to take out one instrument from the slide-rest and substitute another, which has to be set for height and parallelism; and sometimes the slide-rest has to be unfastened and fixed again, nearer to, or further from, the work. I therefore wish to describe a tool which I can guarantee from experience to be very handy, and to do the work of both instruments equally well. I have one of my own in use for about 12 years, and have also made one for a friend, who was much pleased with it. I have never seen a similar one described in any of the books on the lathe. Fig. 1 represents a side view of the instrument, and Fig. 2 a front one. A is the tool-holder, which is brazed into the plate B, which plate has two cone-pointed hardened steel screws E E, Fig. 3, tapped through it, and which engage in two radial V-shaped slots F F, Fig. 4, in the face of the head; these slots are readily made by a properly-shaped drill in the drilling instrument, traversed horizontally in the slide-rest. Of course I have a separate, strongly-made, drilling instrument for work of this kind in metal. The plate, Fig. 3, is clamped to the head by two small screws C C, Fig. 2, which pass through two slots G G in the plate, and thus permit the tool-holder to be set eccentric. I have found 1in. eccentricity to be sufficient, giving a circle of 2in. The eccentricity is read off by a scale of 20ths of an inch, on the side of the plate, with a zero line on the head. The screw-points E F engaging in the slots F F keep the plate radially true, and are much simpler, and equally effective as chamfered guide-bars would be. The screws C C have nicely-squared heads, to fit a small steel spanner D, which has a screwdriver at the other end. The adjustments for eccentricity are very easily made, though some men who have the usual form of eccentric cutter, with the tool-holder moved by a leading-screw having a milled and divided head, may think this a very rude way of doing it; but even in their instruments the tool-holder requires to be clamped with a binding-screw after each adjustment, to guard against backlash of the leading-screw, which would be fatal to good work. I have tried both plans, and would just as soon have my own. Figs. 5 and 6 are views of the working parts of the head and stem. H, Figs. 1 and 5, is the pulley for gut band. The head is coned at I, Fig. 5, to fit the corresponding part of the stem, Fig. 6, for the purpose of taking up wear. The head is secured to the stem by the flat-headed screw K, Fig. 6, the head of which lies in the recess J, Fig. 5, and which has between it and the stem a steel washer L, Fig. 6, which has a square hole to fit accurately the squared end of the stem M, Fig. 6; this prevents the screw, K, tightening or loosening during use. N is a shallow groove turned in the bearing of the stem, and its use is to retain a supply of oil, which is put through the oilhole O, Figs. 1 and 5, which is stopped by a small screw to prevent the oil flying about. The square shank of the stem, Figs. 1 and 6, is fixed in the tool-holder of slide-rest. P, Figs. 1 and 2, is a set-screw, to secure the tool in tool-holder. The tools are readily made from pieces of steel rod. The receptacle for them in the tool-holder is slightly tapered, and I have a corresponding chuck which fits my lathe mandrel for turning them up in, but I have turned them by hand, before I made the chuck, in their place in the instrument, driving it from the overhead. One advantage which this instrument possesses over the ordinary drilling instrument, is that it does away with the necessity of having a number of step-drills of different sizes, for doing some of the ornamental work that Mr. Evans describes, as by having one small-sized flat-ended drill, the tool-holder can be set out to suit any sized step. The best material to make this instrument of is, of course, steel for the head and stem, hardened afterwards, and my own, which is thus made, is in good condition now after 12 years' use. But for those who do not understand hardening work of this kind, and who cannot get it done for them, I would say, make the stem of steel left soft, and the head of gunmetal. The washer, L, must be steel, and the tool-holder with its plate may be wrought iron. By not always placing the same square of shank upwards in the slide-rest, the wear will be more equally distributed. Two more hints I will give. In turning the stem be sure to drill and tap the hole for the screw K first—otherwise you will probably find the head of the screw out of truth. And grind in the head in its place with oilstone powder—not emery; for want of these precautions the work of two friends of mine who made the instrument for themselves, did not prove successful. I may say, in conclusion, that the drawings are not to scale.

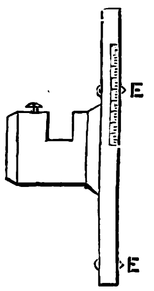

FIG. 3.

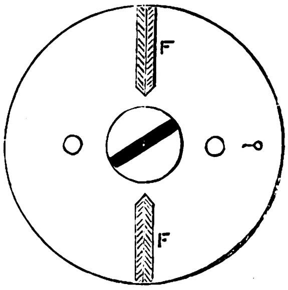

FIG. 4.

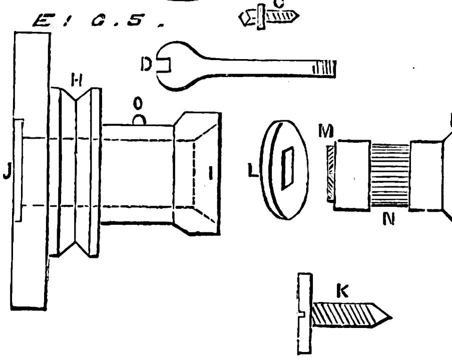

FIG. 5.

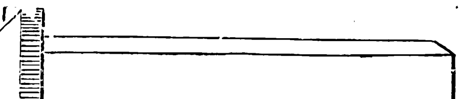

FIG. 6.

THE thirty-third annual report of the Prudential Assurance Company states the premiums on new business completed during the year 1881, in the Ordinary department, amounted to £31,603 4s. 8d., and in the Industrial department to £1,849,494 18s. 5d., the increase in the latter being the largest increase in the history of the Company. The claims paid in the Ordinary branch amounted to £69,677 17s. 1d., and in the industrial branch to £639,752 10s. 1d. The quinquennial report by Mr. A. H. Bailey, states that the general results of that gentleman's searching investigation "cannot but be most gratifying to all who are interested in the prosperity of the company."

M. PLANTE has found that the process of "forming" the lead plates of his secondary batteries is hastened by heating the whole cell during the charging to between 70 and 88° C.

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45392.]—**Manufacture of Soluble Cocoa.**—The description given by Mr. F. B. Cooke (p. 571) seems to apply to what is known as rock or navy cocoa, rather than to the true soluble preparations. Can anyone say how the pure powder cocoas are made, which are readily soluble in boiling water? Two well-known brands bear foreign names, but I believe they are prepared in England.—NUN. DOR.

[45516.]—**Hand-Thresher.**—Many thanks to "Was-heil" for his kind offer of assistance. The thresher is on ground floor; height from centre of drum to floor. I hope "Was-heil" will see his way to help me as nearly as possible in the way suggested, as my floor-space is rather small, and I have plenty of young lads willing to help. Could the attachment not be driven separately, the feed being so light? My own time is so limited, and when the "cleaning" is left to lads, I find a good deal of the grain finds its way into the straw.—D. A.

[45687.]—**Throttle-Valve.**—The two methods are in no respect identical, as, in the first place, I advise the use of metal for case, where you say, use brass. The question at issue is, that on page 549 you distinctly recommend the use of a "circular disc," and I object, and advise that the valve be of oval contour. Please to give us diagrams of the method of attaching "turning bosses" to the ends of an oval, and include the pattern of the "drill" which you say is used to "drill out a hole of flat section."—J. J. A., Liverpool.

[45774.]—**G.W.R. Engines.**—The date of the old 163, I know was 1862, but it is now one of a class numbered from 157 to 166, all of which were built at Swindon during 1879.—N. W., EALING.

[45774.—**G.W.R. Engines.**—In my reply on page 618, last Vol., in the fourth line from the bottom. For "L.C. & D. Co.," read, "purchased ....from the L.R. & D. Co." (Llanelly Railway and Dock Co.), &c.—R. N. H.

[45819.]—**G.W.R. Engines.**—The particulars "T. P." mentions are all of the 7ft. singles, but, since the insertion of my query I have ascertained the information I required. No. 2203 and 2204 are two four-coupled express engines, built at Swindon Works in October, 1881. Inside cylinders, diameter of leading-wheels, 4ft.; driving and trailing, 7ft.; outside bearings for leading; inside for coupled-wheels; no dome, cab; and are fitted with the Sanders vacuum brake. They work the 10.30 a.m. and 1.45 p.m. trains from Paddington alternately.—N. W., EALING.

[45864.]—**Universal Joints in Shafting.**—With the double Hooke joint, up to 140°, I believe. I fail to understand the part of the query about "increase of power"; the universal joint certainly gives no "increase." Yes, it can be done by means, preferably, of cup-and-ball universal joint tied together by one pin.—J. T. M.

[45876.]—**Science and the Civil Service.**—Several; but "Bramelia" must go in at the lower stage—it is always open to him to pass further exams. for higher posts when vacancies occur. He has merely to obtain the permission of his superior officer, and that is rarely refused.—SOMERSET HOUSE.

[45879.]—**Water-Wheel.**—To make use of 2,000 cubic feet per minute, fall 14in. This should be an undershot water-wheel with curved floats, 40 in number; the exterior diameter, 75in.; breadth, 60in.; floats, 11·25in. radial depth. Point of floats at periphery to be nearly angle 0°, with the centre of issuing stream of water passing over the sill and under the sluice. The remaining part of floats may be a portion of a circular curve, but preferably a parabola. The maximum height that the sluice should be lifted (vertically) above the sill is 3·75in. The revolutions of the wheel to be 12·725 per minute. The fluid stream issuing under the sluice should be directed at a tangent to the periphery of the wheel and in its line of motion. The velocity of the periphery should be 4·166ft. per second. The theoretical power of the water is 4·41 h.p., and the actual h.p. that may be developed in a properly-constructed wheel = ·60 theoretical = 2·646 h.p. As peculiar circumstances alter cases, the wheel may be made either of greater or lesser diameter, say from 3ft. to 12ft. The pitch of the floats in the periphery remaining the same, and the number in accordance with the variation in the diameter. A smaller wheel will not give so much useful effect, neither will a larger one, as it will be heavier and cause more friction in rotating upon its journals, besides being more costly. The floats may be No. 16 B.W.G. in thickness, and the wheels with four light plate-iron shrouds; the shaft 3·25in. diameter in the journals.—TUBAL-KAIN.

[45884.]—**Making Gas on a Small Scale.**—I think an apparatus, 3ft. long, 2ft. wide, and 3ft. high, divided into foot lengths, would be ample for a single light. It should be covered with lead-foil, which might be nailed down, the heads of the nails being covered afterwards with solder, to prevent the action of the acid on them. I am perfectly aware that benzoline air-gas does not produce an illuminating flame; but with the hydrogen, which is itself combustible, you only require sufficient carbon to give the illuminating flame. As Mr. Hezmalhalch observes, gasoline is the best for the purpose; but the difficulty of obtaining it in small quantities renders its use impracticable. The gasworks sell a sort of hydrocarbon (they call it carbon), which, when melted and gas passed through it, gives a most brilliant light, surpassing gasoline.—J. KENDALL.

[45885.] —**Yellow Wash for Funnel.** —Yellow-ochre, mixed with pale linseed-oil, and a liberal supply of varnish will do; but the heat will, no doubt, wear it off quick. The only thing is to repaint.—S. M.

[45907.]—**Automatic Musical Instruments.**—The suction principle is unquestionably the best for automatic instruments in which reeds are the sound-producers, and I think that Needham's invention was the first to be described in this country; but I have heard that, in the United States, a caveat had been previously filed in the patent office there by a person named Mc Tammany, and that in some recent suits he has proved his case as the original inventor of musical instruments of the orguinette type. The suction-bellows was, I imagine, unknown in this country, except in the familiar form of the accordion and concertina, until the introduction of the American organ.—GRAY'S INN.

[45943.]—**Pressure of Water.**—What I should require is a 1 horse-power motor to drive soda-water machine. Should I get any more power by using a larger supply-pipe than the makers advertise? And would the water passing through a loose valve stop-cock and meter check the pressure? or should the stop-cock be a straightway or sluice-cock? Also, should I get the 1 horse-power from the motor with a pressure of 36lb. to the square inch?—If "Labor Omnia Vincit" or "Sunlight" will kindly say, I should feel obliged.—WATER MOTOR.

[46007.]—**Turning Wooden Balls.**—If I were going to turn the balls in question I should begin as Wm. Owen has done, by using lengths of stuff. Having the wood properly fixed, first bore the hole say, 1in. up. The bit does not have so much, chance of "running" then. Turn down just where the centre of the first ball will be to the size required. Now mark off ⅜in. length, then take an ordinary turning chisel (not a bead tool, that is cause of the balls breaking off as you say). Now, if you want the balls very true, strike a quarter circle out of a piece of zinc, and use as a template. Apply the chisel, leading with the lower point of the level. Try the template occasionally, and you ought with beech to be able to go down to ¼in. dia. without any breaking off. If you can do them near enough without the template, don't use it. Expect to be foiled in the first few attempts; but when you have had a little practice you will turn out some smooth shiny round balls which will entirely satisfy you.—W. W. M.

[46061.]—**Model Engine.**—To "Sunlight."—The cylinder is of the beam-engine class. I want an externally-fired horizontal boiler. Will 3-16in. plates be thick enough for it?—Mechanic.

[46069.]—**Automatic Arrangement.**—I beg to suggest fitting up drum on vertical spindle (axis vertical); just a cylindrical tray or box in divisions. Projecting from lower side, at middle of each division, a pin or tooth-clack, to work a worm-screw, which said teeth take into. Say that worm revolves once every five minutes; then have three threads on it. At six o'clock set shaft carrying worm with that part of thread at which tooth leaves worm facing point of tooth (to make tooth take into worm right); turn box so that tooth at middle of first division is up to other end of worm and set a-going. Worm will keep middle of this division, under aperture, fifteen minutes, and then shift box at once to middle of next division: box to be shifted by a turn of cord round centre spindle (below box), and over a pulley with weight attached. The advantages of this plan would be, the partitions would pass aperture rapidly, and therefore insure greater accuracy. Divisions need not be all one size (the checks will likely come thicker at one period than another), and construction as simple. Put an extra half-thread on worm; it will be better than exactly three, and keep box same time in position. Would Mr. Lancaster kindly give his opinion of this plan?—S. W. M.

[46076.]—**Governors.**—I can quite indorse "Sunlight's" views about governors. My engine, a semi-portable, driving brick-machinery, was sent out with an old-style disc-tube, and a nice trouble it was. The nature of the work requires a very sensitive, quick-action regulator, as the load is continually varying as the pan is supplied with material. The engine-tenter could never leave his engine for five minutes, or it would start racing, tearing the belt to pieces, breaking gear, and playing the deuce generally, unless he was on hand to shut off steam by hand. I had an equilibrium valve put in and all was changed, the engine running as steadily as can be desired, and, if a belt runs off, or one of the machines put out of gear, never get up extra speed; though, for want of space, I only had a 4ft. fly-wheel to steady two 11in. cylinders, working at 75lb. pressure. The disc-tube seems to be unable to control an engine whose work is variable, and, when the load is steady, a governor is hardly needed at all.—Treadle.

[46082.]—**Driving Smith's Fan.**—Will J. Perry be kind enough to say when and where I can have ocular demonstration that a man can turn a 6in. fan at the rate of 3,000 revolutions per minute for any reasonable length of time, so as to get through the ordinary routine of a smith's shop? Then, in return for his kindness, I will show him how to make a perfect "weld" with a piece of hot to one of cold iron. Query: Can he weld a 4in. square cart-axle with either of his fans?—J. J. A., Liverpool.

[46083.]—**Tanah-Ampoh**—Is Kaolin, a soft, white earth, probably of organic formation. It is eaten by the Javanese, not as a delicacy, or even as a matter of course, but in emergency. The Malay word "perampohan," woman, is evidently a derivative.—R. B.

[46099.]—**Bronzing Brass.**—Take 1oz. crude flour-sulphur, ¼lb. of pearlash; mix well together, and place in an iron ladle, and put it over the fire, and keep stirring it until you get it well mixed and forms a reddish-brown mass; turn out upon some stone; when cold, pour about 3 pints of boiling soft water upon it, and when settled, pour off the clear for use. When your article is cleaned, dip until dark enough. They will not be dark by immediately dipping, but must be hung up for a time, and dipped again; but the articles must be thoroughly free from dirt or grease, and dipped into nitric acid before being dipped in the above. It is all a nosegay to use.—Jack of All Trades.

[46100.]—**Lever Escapement.**—You will find it difficult to alter the pallet-stones. You must put the escapement closer to the escape-wheel. You will find (if it is an English lever) that the holes are drilled out of the centre in a bush which is fitted in the plates; by shifting the position of these bushes you will be able to get the escapement nearer the escape-wheel. But I think you will find the following easier and less likely to deface the surface of the plates. Broach (or rimer) the holes larger, and file up a piece of brass wire to fit the holes you have made larger; now drill a hole out of the centre of the said brass wires; now fit the brass wires (which we will call bushes) into their holes, and put plates together with escape-wheel and escape, when, by turning the bushes, you will be able to adjust the escape to a nicety; by pressing the bushes against the shoulders of the escape, you will make it sufficiently tight so that it will keep its position while you try its depth, first one side and then the other. Now break off the bush (which has been previously cut the same as a bouchong), and place your plate with the inside of the bush resting on a riveting shake, take a round-head punch that will fit the old chamfer, and rivet the bush so that it shall not shift. This will leave your inside level with the plate, and your outside the same as before, with this exception—that the hole will not be in the centre of the chamfer. If the head of your punch is nice and smooth, your chamfer will be bright. You must not use any cutting tool for finishing, not even turkey stone. So sure as you do, you will spoil the surface of the gilded plates, and that is what you should always try and avoid. You must always bear in mind that escapements are made by practical and experienced men and good machinery, and you will hardly ever be able to better them. Also wheels may be spoiled but never improved.—A Fellow-Workman.

[46109.]—**Lathe-Oil.**—I think "A. T. F." must be mistaken in ascribing the clogging of the lathe to paraffin. I have always found it a most admirable oil for removing stickiness or old oil; but it is too volatile to use alone as a lubricant. I have tried all manner of oils. No vegetable oil ought ever to be put to good machinery, as they all corrode iron and steel. Castor-oil is the best of them, but it smells horribly when warm. I settled finally on half sperm, half paraffin, and found the mixture admirable for all shop purposes. In fact, the so-called "sewing-machine oil," "tricycle oil," &c., &c., are, I believe, just this mixture, and nothing else. For oil-stones, there is nothing like paraffin by itself. Also, to wash your hands in, after an extra dirty job, when soap and hot water won't fetch the grease out. Finish with soap and water to remove the paraffin.—Treadle.

[46117.]—**Daniell's Battery.**—I beg to thank Mr. Lancaster and others who have replied. This is a 10-cell battery in a long teak box, lined throughout with marine glue, with slate and porous slabs fixed alternately in grooves imbedded in the glue; zinc and copper plates coupled, charged with sulphate of copper in solution with copper plate, and water only with zinc plate. It is precisely the same as used by P.O. for telegraph work, and as I wanted a constant battery of a certain power for experiments, I thought this would answer my purpose; but hitherto it has been entirely useless. I was aware that I could quicken the action by the addition of acid, but I thought wrongly. I believe now that it would destroy its constancy to do so. With respect to the form of Daniell recommended by Mr. Lancaster with copper cell, it seems a good idea, but it struck me that unless used with great care, it would be very liable to become "short-circuited." I have lately changed three pint double-fluid bichromates into Bunsen, and am delighted with the change. I get all the power I want, and can use them continuously for four hours, and that is about as long as one ever wants them at a time. My great trouble is with the zincs. The zinc of commerce is such wretched stuff that, do what I will in the way of amalgamating, the acid will find its way in, and soon through the zinc. What I should like would be to change my 10-cell Daniell into Bunsen. Could I, and if so, how?—A Young Beginner.

[46118.]—**Slide-Valve and Piston.**—I have done as you told me, and I find that the valves leak. What should I do to make them tight? I have done engine valves, but don't mind taking a little advice from "Sunlight" or "L. O. V." Hoping they will oblige.—R.

[46120.]—**Oil Painting—Preparing Canvas.**—One part white-lead, two parts whiting; a small portion of litharge of lead and sulphate of zinc for driers; mix with equal parts of boiled linseed oil and raw linseed, tinted with either brown umber or lamp-black, for a neutral ground. The canvas was tacked upon a stretching-frame, and sized with weak glue-size, to which a small portion of zinc sulphate was added; when dry it was stippled over with some driers and raw linseed oil as thin as possible, not saturated. When very near dry, the white-lead, whiting, &c., was mixed up very smooth, and put upon it very thin and smooth with a large palette-knife, and hatched over with a large sash-tool, drawing it across one way and then at right angles until the face presented a face like a piece of fine linen or cartridge-paper, when it was left to dry.—Jack of All Trades.

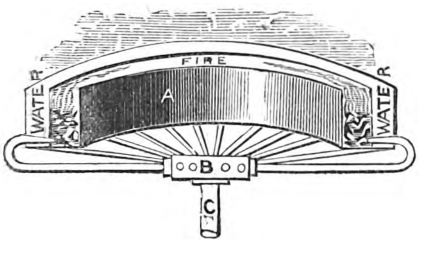
[46129.]—**Adhesive Weight of Locomotives.**—To "Guide Yoke."—The formula you have applied is used to determine the leading elements of the machinery. In order, therefore, to design an engine capable of performing a given work, it is necessary to deduct one element of the formula, $T = k\,d^2l\,/\,D$, the three others being already chosen. But this is not sufficient; there is a primary relation or inequality which has to be satisfied above all. It is, adhesion weight $\times f < k\,d^2l\,/\,D$; f = that co-efficient by which you multiply the weight on wheels to obtain the adhesion. For it can be proved easily that the tractive power of a locomotive engine is equal to the friction the driving-wheels develop on the rails. This friction or adhesion is represented by adhesion weight $\times f$ in the above formula of inequality. In order to move the train, the tractive power must be equal or superior to the sum of the resistances opposed to its motion at the intended speed, and not inferior to the adhesion or adhesion weight $\times f$. In return, if the adhesion is too little, the train will not move forward, but slip; as the adhesion weight may be considered as constant and f variable, this slipping will take place sometimes even in the best of engines when f has become low. It is known that f varies from 1-10th to ¼, the former value corresponding to very damp weather and ¼ to very dry of the same; 1-6th is the average value in our climate, but 1-5 or 0·2 is generally taken in the calculations of engines, for in that case we are sure to be well outside the requirements of an increased friction. One of these is already met with when we leave a station, for the friction at starting is greater than at full speed. It follows, from all what precedes, that the manner of calculating the elements of a locomotive is as follows:—Reckon the resistances opposed to motion caused by resistance of air, friction of journals, &c. (including engine and tender) at the intended speed. The result expressed in pounds multiplied by 6 expresses the load to be borne by the driving-wheels to obtain sufficient adhesion under ordinary circumstances. The same result multiplied by 1·2 will give the tractive power, or rather its maximum, a number by 1-5 greater than the adhesion obtained in taking only the sixth part of the above-determined adhesion weight. When the coefficient $f = 1/5$ and a full load is on the engine, which load is the maximum work to be done, the mean pressure is that obtained by the least cut-off—viz., when the link is lowered (or raised) to its full extent. Should the load be less than usual, the engine would not work very economically in these circumstances. When f decreases, the adhesion consequently decreases: it would not be much more economical to keep the same grade of cut-off. Take a less train in this case. It can be seen that engine-driving is not an indifferent affair. When you go down an incline, turn the handle of your screw reversing gear towards the middle of the stroke of its block. Abroad, and particularly in France, on the Chemins de fer du Nord and Midi, they have adopted the habit of marking in the cab of the engine the power in special units that can be developed by the engine under ordinary circumstances. A list of the engines, with the number of units they exert, is drawn up, so that the railway officials can judiciously compose their trains according to the tractive power at their disposal and the state of the weather. I shall conclude by working out the following example:—Required to find the proportions of cylinders of an engine to draw regularly a load of fifteen carriages weighing full 11 tons each, at a speed of 45 miles an hour on overruling gradients of 1 in 200, weight of engine (pre-supposed) with tender 63 tons; diameter of driving-wheels, 7ft. Weight of train $= 15 \times 11 + 63 = 228$ tons. Resistance per ton at 45 miles an hour, on 1/200 ascending gradient = 40lb. Total resistance $= 228 \times 40 = 9{,}120$lb. Multiplying by 6 and dividing by 2240; $9120 \times 6 / 2240 = 24$ tons, 8cwt. on wheels. Whence it follows that the engine will be a four-coupled locomotive. Multiplying by 1·2, we have $9120 \times 1{\cdot}2 = 10944$lb. tractive power, or 11000lb. in round numbers. Both diam. and stroke of piston are unknown, so is also the pressure; for the latter, let us choose 140lb. sq. in.: high pressure is economical. Admitting 1-10 loss of pressure to the cylinder, and 2lb. back pressure, the initial pressure is about $(140 - 14 - 15 - 2) = 109$, and taking ¾ of stroke as longest admission, then: Mean effective pressure $= 109\ (1 \times \log._{\varepsilon}\ 4\text{-}3\ /\ 4\text{-}3) = 105$. If we choose the stroke = 1·5 diameter, we have finally, x being this diameter, $11000 = 105 \times 1{\cdot}5\ x^3/84 \quad x = \sqrt[3]{11000 + 84/157{\cdot}5} = 18{\cdot}\ldots\ldots\ldots''$ the diameter being 18, and a trifle over. We shall take, therefore, 18in. for the diameter and 27in. for the stroke, for this gives when verified by the usual formula, $105 \times 324 \times 27\ /\ 84 =$

10935lb. a result not far off 10944. Had we chosen 1-6 of adhesive weight for tractive power, the results would have been different; but the engine might not have been able to perform its duty when the co-efficient of adhesion would have, I say, risen to 1-5. Should the co-efficient = 1-6, and the load less, such as 132 tons for the train, and cæteris paribus, the pressure will average 73lb., which would correspond to a cut-off at ⅜ stroke. To sum up, our engine is so calculated as to make it sure that it shall take regularly and under ordinary circumstances the working load, 228 tons. Some single engines have unusually large cylinders, such as the 8ft. on the G.N. Railway, and the 7ft. of the narrow gauge of the G.W. This would seem anomalous if it were not explained that these cylinders are capable of giving long expansions; in fact, the sectors of the reversing gear are finely notched. A long link should always be adopted when large cylinders are employed, with a view of prolonged expansions. Sometimes it happens, as I noticed abroad, that engines have no sufficient adhesion for the cylinder power: an additional mass of cast iron is resorted to—it is a miserable expedient. At the next big repairs, it is found necessary to reduce the diameter of the cylinders. The opposite is also met with: heavy engines, like the last express of the French Western, who have their cylinders too little. Of course, in these matters, the designing of a new engine is rather made dependent upon what has been done previously. I hope to have convinced "Guide Yoke" that adhesion plays a very important part in the designing of a locomotive, that the elements being determined after it, the formula $T = K\,pd^2\,l / D$ has a maximum, and is only resorted to to see whether the load to be conveyed under certain conditions is within the maximum—namely, the adhesion at a high coefficient of friction.—Ed. Gobert, B.Sc. (Paris), 39, Heskey-street, Nottingham.

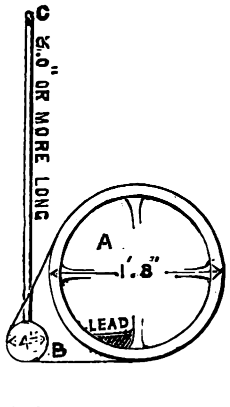
[46132.]—**Fluoric Acid for Soldering Iron.**—The following recipe was given me by an old hand for brazing cold or welding without heat. I have not yet had occasion to test it, but it is at the service of "Thanks." Mix in a guttapercha bottle, ½oz. fluoric acid, ½oz. nitric acid, ½oz. bismuth (metal), ½oz. brass spelter. Rub the above on to the broken parts, and close tight together for a minute. I would advise "Thanks" to be careful not to get any of the mixture on his fingers or hands.—W. W.

[46133.]—**Stencil Plates.**—Are best cut out with a narrow scorper—that is, a species of graver, whose section is of an acute lance shape. You can get them any section up to a knife or parting-scorper. The metal is either zinc, copper, brass, or silver, and German silver. These about 20 or 22 B.W.G., or the thin lateen brass is used by some, such as was used for French clogs (used to be called by some clog-brass); this is silvered or electro-plated, in many instances, which gives it a finish.—Jack of All Trades.

[46140.]—**Gas for Heating Iron Hoops.**—If "J. W. Smith" cares to follow out my idea as shown in sketch, I think he will find that it is cheaper to use the ordinary blacksmith's coke than to go to the expense of heating by gas. I have never seen anything after the same design as this. It could be adapted in the same manner for gas, by introducing a burner where the small tuyere is shown. A is a circular trough about 9in. deep, with a partition 3in. from the outer edge and running all round; the other space 6in. wide is for the fire and the hoops, the small space to be filled with water to keep the pipes cool. B is a cast-iron chamber attached to pipe C, which is in connection with a fan. The elbow-pipes as shown leading out of it should come into the trough at about 6in. apart and pitched off all round the said trough. Shall be glad to give further information if required.—Pattern-Maker.



[46148.]—**Fret-Saw and Lathe.**—A. My fly-wheel is 20in. diam., and heavy; this drives a drum with leather belt, the drum being 4in. diam. and about 1½in. thick, wood, as at B. This means five strokes of saw to one revolution of fly-wheel. I made a saw as well as I could, and Messrs. W. Makin and Sons, of Sheffield, made me some from my pattern; one saw thus made is worth a gross of the rubbish which is usually sold as saws. The connecting-rod should not be less than 3ft. long; but as much more as you like, as at C. What



thickness and class of wood does "J." intend cutting? More particulars if wanted.—Wm. Hosken, Penryn.

[46149.]—**Oil for Lathe.**—There is nothing I find better than some good lard-oil, with from 1 to 2 parts paraffin.—Jack of All Trades.

[46149.]—**Oil for Lathe.**—No one denies the fact that by successful lubrication a large item may be saved in a works where there is much machinery, and that even where there is but little, this item in a short time becomes more or less appreciable. Yet in spite of this, it is a very remarkable fact that there exists an almost universal ignorance of any scientific basis for lubrication. In a paper published in this journal (Feb. 17, 1882), I endeavoured to show that such a basis was to be founded on viscosity. That for light machinery we require a "thin" oil, and for heavy machinery a "thick" oil; and that, commencing with light machines and gradually advancing to the heavier ones, the viscosity of our oil must also gradually increase. And there can be no doubt but that if this simple rule be adhered to, we shall have the most economical, and at the same time most perfect, lubrication. "Cloture" asks what oil is most suitable for a lathe. Firstly, let him procure some American mineral oil of about 900 specific gravity, and some pure rape-seed oil; secondly, let him mix the two together in the proportion of one part of rape-seed to four parts mineral; thirdly, let him give his lathe a good cleaning with paraffin oil, and then lubricate with his mixture. If it should be a little too thin he can add more rape-seed; if a little too thick he can add less; by a little practice he will get an oil that exactly suits his lathe, and which neither stiffens nor clogs. The above makes an oil suitable for all light machinery. It may be mentioned that "paraffin" oil is quite unsuitable for lubricating purposes, on account of its being readily decomposed.—Thomas Farmer.

[46149.]—**Oil for Lathe.**—It is rather a difficult question to decide, there being so many opinions upon the subject. I have, however, given a deal of attention to it, and after trying many kinds, I am quite sure that there is nothing better than animal oil; it has more lubricating properties, although, at the same time, it is more corrosive, but this can be overcome by a process of refinement. We have for many years used nothing but the best neatsfoot oil, which I refine through charcoal filters, which latter, by the way, consist simply of a tin cone with a series of small holes towards the point: it is filled two-thirds with fine powdered charcoal, and the oil then placed on the top. It will take a long time to get through, but when it does it is perfectly clear, and quite free from corrosive matter. A few drops of paraffin I find an improvement. There is a deal of waste; but we use it all up for rough drilling purposes in the works. On an average I calculate upon getting only a 4oz. bottle from a quart of oil; probably this may be thought a roundabout way of obtaining oil; but as a small quantity will go a long way, and not make the bearing dirty and sticky as if glue instead of oil had been used, it is worth the trouble. I find it preferable to the Rangoon; for guns, &c., it has also been found the best.—J. H. Evans.

[46154.]—**Potash Carbonate.**—I should like to ask Mr. Duff whether he has ever prepared potassium-carbonate from potassium-sulphate in the way he directs "Pearlash" to proceed? I must say I am rather inclined to doubt.—Analyst.

[46156.]—**Pendulum Spring.**—Your question is not sufficient for a proper answer. Your hair-spring should lie uniform with the centre hole in cock-bar. It may be that the spring is too large. Is the stud (i.e., where the hairspring is pinned) shifted? If there is sufficient room between the coils you may sometimes alter it by opening the outer coil opposite the stud; but if the spring is too large, you can only make a good job by putting in another.—A Fellow Workman.

[46157.]—**Secondary Batteries.**—Apropos of Mr. Lancaster's remarks under this head on p. 622, may I venture to point out to that gentleman that we learn more, very often, by records of failures than by descriptions of successes. I suspect I am not alone in thinking that if Mr. Lancaster has been experimenting with secondary batteries—even if his experiments have not been satisfactory—an account of what he has done would be useful. —Nun. Dor.

[46160.]—**Birmingham Wire-Gauge.**—The relative values in decimals of an inch, of the Birmingham wire-gauge, are as follows:

No. B.W.G.	Ins.	No. B.W.G.	Ins.
0000 =	·454	17 =	·058
000 =	·425	18 =	·049
00 =	·380	19 =	·042
0 =	·340	20 =	·035
1 =	·300	21 =	·032
2 =	·284	22 =	·028
3 =	·259	23 =	·025
4 =	·238	24 =	·022
5 =	·220	25 =	·020
6 =	·203	26 =	·018
7 =	·180	27 =	·016
8 =	·165	28 =	·014
9 =	·148	29 =	·013
10 =	·134	30 =	·012
11 =	·120	31 =	·010
12 =	·109	32 =	·009
13 =	·095	33 =	·008

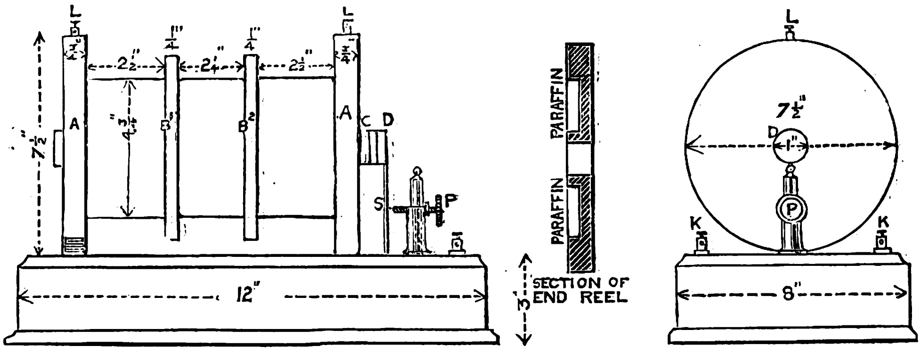
15 =	·072	35 =	·005
16 =	·065	36 =	·004

—T. R. Saxton.

[46161.]—**Pumping to Pressure.**—The main from the pumps joins an 8in. main 500 yards from my engine-house. The 8in. main acts as a supply to the town, as well as a supply to the reservoir while pumping at this junction in the valve, and also the 3in. main branches off, and go side by side, the 8in. main to the reservoir, and the 3in. main 200 yards farther on, supplying, on its way, 18 villas. The reservoir is 800 yards from my engine-house, and the end of 3in. main 1,000 yards. I have thought, would it be practical and economical to fix a double self-acting valve on the 8in. main in the reservoir, weighted to 15lb. to the square inch, to pump against, so as always to have pressure enough while pumping to supply the high level, and when the pumps cease working, the other valve would open with the pressure from the reservoir, and so do away with walking 200 yards twice a day to open and shut the valve. If "Sunlight" or "Labor Omnia Vincit" will assist me, I should feel obliged.—Water Motor.

[46162.]—**Nascent Oxygen.**—Surely John Pickering makes some mistake when he inquires "under what conditions (if any) it may be dangerous to decompose chlorate of potash with manganese, by using for the purpose sulphuric acid." In the first place, manganese does not decompose chlorate of potash; but simply assists the action of heat thereon, without undergoing any apparent change in itself. Such action by contact, of which there are many other examples, has been called for want of a better name catalysis: its true nature is not clearly understood. The action of sulphuric acid upon chlorate of potash produces, not oxygen, but a very unstable gaseous compound of chlorine and oxygen called chloric peroxide (Cl_2O_4), which is decomposed with explosive violence by the mere warmth of the hand. Any attempt to prepare oxygen from such materials would certainly result in what John Pickering seems anxious to avoid—a dangerous explosion. Manganese, or more properly manganese dioxide, yields one-half its oxygen when heated with concentrated sulphuric acid; but the gas thus obtained is generally mixed with more or less carbon dioxide, derived from the carbonates nearly always present in commercial manganese; for this and other reasons the process is not to be recommended as a source of oxygen. Where it is required to apply oxygen in its nascent state, we generally employ certain substances containing a large amount of oxygen held by a very slight degree of chemical force, such as chromic or permanganic acids, which readily give up their oxygen to any oxidisable substance. If John Pickering will state to what purpose he wishes to apply nascent oxygen, I will try to recommend him a suitable oxidising agent.—Analyst.

[46153.]—**Induction Coil.**—In reply to "J. A. W." I send the following description with full drawings of a 1in. (spark) coil I have made. 1. *The Core.*—I made this of soft iron wire, size about 20, by first cutting it into lengths of about 10in. long, rolling them straight between two boards, then making them up into a round bundle 1in. in diameter. I twisted a piece of soft wire around them and placed them into a fire to soak for several hours, and then let the fire die out. The core was now soaked in melted paraffin for some time, and on taking it out, as I took off the wire binding the core together I twisted on a layer of soft cotton tape, and then soaked again in melted paraffin. II. *The Primary.*—I used two layers. No. 18 silk-covered, each layer insulated with paraffined foreign note-paper, and wound on the soft cotton tape of the core. After the first layer was on a smooth surface was made by ironing in paraffin with a flat iron previous to putting on the layer of foreign note-paper. I then soaked the whole in melted paraffin for some time. III. *The Tube.*—This I made of dry brown paper and glue wound round the primary until the tube was about 1-16in. thick. The whole was then soaked again in melted paraffin for some time. IV. *The Secondary Wire.*—Before commencing to wind the secondary, I prepared my end reels A A in the figure by turning them of hard wood, very dry, and filling up the space marked paraffin in the Figure with melted paraffin, after first soaking the ends in melted paraffin for about an hour. I divided the space on the tube into three parts, as shown in the Figure, with ebonite discs B B, as I had two pieces of sheet ebonite by me; but should not have bought it on purpose, but should have wound the secondary from end to end. The secondary consists of one pound No. 36 silk-covered wire from Rickards', Derby (I have always found their wire to be very good). The division to the left was first filled, one end being fixed to the binding-screw L, the other end passed through the ebonite disc B¹ and passing down close to B¹ on its right-hand face, with a disc of stout paraffin-paper to further insulate it from the secondary wire in the middle compartment, and so on for the third division, finally finishing at the other binding-screw L. Each layer of secondary is insulated with two layers of paraffined foreign notepaper, ironed on with a hot flat-iron. I used throughout plenty of paraffin. N.B. Take care to wind each compartment in the same direction. V. *The Stand.*—The base contains the condenser of sheets of tinfoil and paraffined foolscap paper, built up sheet by sheet until the spark at the spring S almost ceases, and connected the one series to the pillar P, and the other series to the spring S. K K are the primary screws for the battery connection. The ends are black varnished. I have used this coil with all kinds of batteries, and can get 1in. sparks—good thick sparks with a small four-cell Grove battery. I am now building a 12in. coil on the system of discs of paraffined paper with slices of coil between them, particulars of which I shall be glad to send when completed.—T. N. Andrews, Plymouth.



[46166.]—**Rangoon Oil.**—This is a lubricant with a basis of mineral oil, sp. gr. about 905. If it smells strongly of tallow, in all probability tallow or some other animal oil has been mixed with it to increase its lubricating power. It can hardly be called an adulteration, as "mixed" oils are more suitable for lubricating purposes than pure mineral, and again, any mixing oil, animal or vegetable, would be more expensive than the pure mineral oil itself. I do not think there is any degree of probability in the statement that the oil is made from the refuse of candle-manufacture. In future "Armourer" cannot do better than use pure mineral oil; he will find it to give him every satisfaction.—Thomas Farmer.

[46170.]—**Bending Wood.**—If you want to bend wood for furniture you must have it green and steam it, and for many purposes a breck is used; that is, two half-round pieces of wood bolted with the convex sides facing one another, with distance pieces between. The timber is put between these a short distance at the time when wet and hot, and gradually broken or bent, as you would a bar of iron for a cart-tire, and then taken to the moulds to be set up to what shape it is wanted; but sawn timber, unless very straight-grained, will seldom bend, and you can scarcely ever depend upon it; rift wood is the best for the job.—Jack of All Trades.

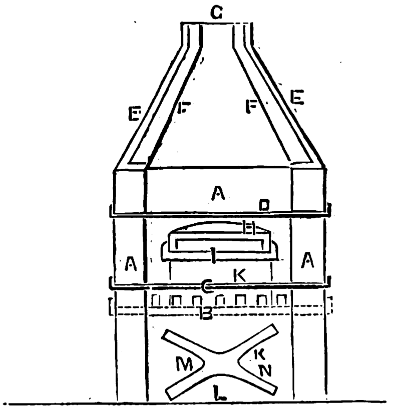
[46173.]—**China Paintings.**—See reply 46189; this will suit you, and you can mould your seggars or muffles to what shape you like.—Jack of All Trades.

[46176.]—**Burnishing Ink for Edges of Boots.**—Make a strong solution of nut-gall, 1oz. to half-pint of water, boiling; pour off the clear and add 3oz. acetate of iron, put no gum in it; but when dry, damp it with gum and rub round with a rag and tallow, and stick up with long stick, shoulder-stick, or jigger.—Jack of All Trades.

[46184.]—**Wringing-Machine Rollers.**—Here, again, I differ with "Sunlight." A flat plate with a square hole at the end of a roller, reversing its action repeatedly, is, I hesitate not to say, a very bungling way to endeavour to secure any axle. When making the windlasses used upon Ballarat gold-diggings (sinkings over 200ft.), we procured a barrel of, say, 6ft. long by 10in. diameter, of the best timber to be procured. Then a ring of 1¼in. by ¼in. iron was shrunk on at each end; next, a smaller ring, say, 2in. deep and 4in. diameter, bevelled to a cutting edge, was driven into each end. The spindle, where entering the axis of the barrel, was square, and, say, 1¼in. iron, 14in. long, slightly tapered at point, deeply "ragged" with keen cold chisel, and driven home with heavy forge-hammer into an auger hole, smaller than the square of the shaft, then brought to run true by wedges of iron.—J. J. A., L'pool.

[46187.]—**Watch and Clock Repairing.**—I hope that the instructions I gave "Hopeful" last week have proved of service to him. I here continue my reply to his letter. Respecting the fitting of new springs to Geneva watches: In either case, whether the barrel is a suspended one—i.e., one fitted with a solid arbor and ratchet-wheel, and not pivoted in the plate; or one which has the ratchet-wheel held on the arbor square by a screwed cap, and having a bearing in the plate—the stopwork must be removed, or at least the part fitted on the arbor. The star-wheel need not be removed unless dirt has collected underneath it. Having, then, removed the "stop" from the arbor square, take out the barrel lid by inserting a tool-point in the hole therein, and with a gentle leverage forcing it up. Whatever the make of barrel may be, the procedure as regards the stopwork is the same. In this particular instance, the barrel being a suspended one, I will limit my remarks to that. Some of the old makes of Geneva watches have the barrel lids between the barrel and the cock, while the more modern ones, excepting in few instances, have the lids underneath. If the watch in question has the lid underneath the barrel, the new spring may readily be coiled and wound in, by the inner end being hooked on the arbor-roller, and the arbor turned with the key, the left-hand thumb meanwhile being held firmly against the hooked-up spring during the process of winding. Previously, however, to doing this, the spring will have had to be measured off to the correct length; and the old spring will be a guide to this. If you have a gauge, and the new spring is the same thickness as the old one, you will, by that means, be pretty sure to get the correct length. A hole must be made at the extremity of the new spring, after it has been softened, about half an inch up it. This end of the spring must be made a little thinner than the remainder of the spring, if the hook in the barrel is a short one. If fairly long, it does not matter. Having wound the spring in the barrel and seen that it is safely hooked at both ends, and down level in all its coils, apply a small quantity of oil to it, and replace the lid. On looking closely round the edge of the barrel a drill-mark will be found. Place the hole in the barrel lid over this mark, press the barrel lid home to its seat, by holding the barrel in both hands and bringing it against the edge of the work-board. Do not use nippers to close it up, as many do, and thereby disfigure the barrel, and probably cause the spring to be bound. Now put a key on the square at the winding end, and fix the key in the vice. Wind the barrel round until the spring is felt to pull fairly, place the steel stop on the square, the polished side up, and set it, and the wheel, so that when the barrel is released the stop will prevent it unwinding any further. If the square is drilled for a pin, insert one, and keep it short and close. Now, holding the barrel very firmly by both hands, turn it round and round until it is found to stop securely against the star wheel. If all is rightly done, let the barrel revolve gently until down, and the operation is then complete, and, after brushing, is ready to be screwed in its place in the plate. It occasionally happens that when a mainspring breaks, one or more teeth become a little bent, so the teeth should be examined for this possible defect, and if found damaged, be corrected. This may easily be done by placing the edge of a penknife at the base of the tooth, and gently, but firmly, forcing it upright.—Alfojoe.

[46189.]—**Muffle for Firing Painted Glass.**—I give you a sketch which I think will suit you



A A A furnace, built of firebrick, inside 18in. wide, 15in. deep; B A, bar of iron for carrying firebars, of which there are two, one 3in. from back and the other front; the bars are all loose iron bars ¾in. sq.; C, bar to support brickwork-front up to opening for muffle, which should be 5in. or 6in. deep; then an opening 6in. and bar D to support upper brickwork about 9in., and the top E E may be of cast iron, lined with fireclay and sawdust; F F G flue, about 8in.; when lined with clay, about 4½in. opening; H muffle, consisting of two tiles, made of a mixture of pipeclay and fireclay, with sawdust, pollard, or fine charcoal-dust. 1, the bottom or bed; this should be covered with very finely-sifted air-slacked lime to bed the glass upon, made very smooth and level; the dotted line K is the stand for muffle to rest upon, made of the same material, the shape shown K. L is the ash-pit; the opening where the muffle is placed in may be closed with a cast-iron or wrought-iron box, lined with fireclay, with an opening in the centre in which a piece of brick may be put in loosely that it may be examined from time to time; and when it is vitrified you may either drop the fire or take the muffle out with a slice or peal, and pop another in its place; the whole of the bars may be taken out but two, M and N, left for the stand and muffle to rest upon; chimney about 12ft. high.—Jack of All Trades.

[46190.]—**Beat in Violoncello.**—To "Fiddler."—The 'cello is a small-sized one (youth's), and I strung it as an octave violin,—i.e., took away the C string, moved G, D, and A one peg lower, and added a thinner one for E. With its proper strings and at usual pitch the beat disappears; but I think I like the tone better when tuned G, D, A, E,—clear and more ringing, though good both ways. Further information will be valued.—Kanet.

[46193.]—**Staining of Floors.**—You should not use size—it is sure to look patchy; use beer.—Jack of All Trades.

[46195.]—**Photo. Washing-Machines.**—There are a great number of washing-machines, each one having some good point. You should get the catalogues of the different makers, then pick out the one most suitable to your requirements and make one for yourself.—W. J. Lancaster.

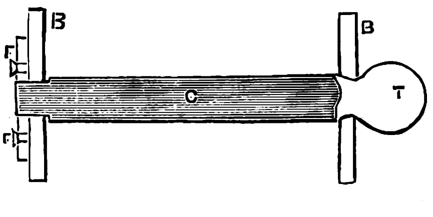
[46200.]—**Photographic Transparencies.**—You can take transparencies either by the old wet process, or on gelatine dry plates; but gelatine films will be useless to you: they would cockle when put into the lantern. You can take any number of transparencies by superposition, or much better in my phantasmograph; this is a chamber 12in. long, with a place at one end to hold the negative and dry plate, and a door at the other end to allow of correct exposure; the plates may be developed to any required tone, and will produce excellent transparencies.—W. J. Lancaster.

[46201.]—**Largest Gasometer.**—The dimensions of the gasholder for South Metropolitan Gas Company is as follows:—Inner lift, 208ft. diam. by 53ft. 6in. deep; middle lift, 211ft. diam. by 53ft. 3in.; outer lift, 214ft. diam. by 53ft., thus having a total height of 159ft. 9in. It has the greatest height and largest capacity of any gasholder that has ever been made, but I believe there is a gasholder 220ft. diameter, but has only a height of 90ft. It has a capacity of 5,500,000 cubic feet. The total weight of standards and body for this gasholder is 1,400 tons. The gasholder was made and erected by Messrs. Ashmore and White, Stockton.—M. Rees.

[46204.]—**Geometrical.**—There is a slight error in the reply given to this last week, arising chiefly in the computation of the area of the triangle; the area of circle is 1866·55; of sector, 1274·18; of triangle, 270·86; of required segment, 1545·04 square feet.—W. A. S.

[46205.] — **Induction-Coil.** — Double-covered wire takes up too much room: better have good single-covered and wind as closely as possible. I have seen coils made up with naked wire and unspun silk line run together, thus forming a thin layer between each successive coil of wire; but this takes up more room than nicely-wound wire, and consequently reduces the capabilities of the coil when finished.—W. J. Lancaster.

[46205.]—**Induction-Coil.** — I have made a small one which acts as well as any I have seen with the same amount of wire, and I wound both secondary and primary with single-covered wire, insulating the layers from each other by thin note-paper (foreign preferred). With regard to the latter part of query, as to the size: — Does "R. L. J." mean, (1) length of wire? or, (2) length of core? Certainly the strength of the induced current depends upon the length of wire, and the longer the core the stronger the current. (1) Because the magnet will be stronger, the poles being farther apart; (2) The longer the core the nearer the outside layers to the magnet, and, therefore, the more power the magnet has upon the secondary, for the magnetic force (as all other forces) "decreases inversely as the square of the distance"—*e.g.*, suppose a layer of wire is 1in. away from the core, the strength of the current is, say, 1. Now, suppose it to be 2in. away, and the strength of the current is $1/(2)^2 = \frac{1}{4}$; at 3in., it is $1/(3)^2 = 1\text{-}9$ at 4in., $1/(4)^2 = 1\text{-}16$, and so on; but do not carry this principle too far, or else you will have an unsightly instrument. The following is the sizes of the one that 1 made, which gives (with 1qt. Bunsen cell) a $\frac{1}{4}$in. spark with condenser. Core: Length, $2\frac{1}{2}$in.; diameter, $\frac{3}{8}$in., composed of a bundle of No. 18 iron wire. Primary, 4 layers of No. 20 silk (single) covered wire, about $\frac{1}{2}$oz. Secondary, $2\frac{1}{4}$oz. of No. 36 silk covered wire. Diameter, when all the wire is wound (with paper) $1\frac{1}{4}$in. The condenser consists of 24 pieces of tinfoil, 4in. by $1\frac{1}{2}$in. separated with paper. If "R. L. J." wants his coil for administering "shocks" to the human body, I should recommend him to use, as a regulator, a piece of brass tube made to slide over the core. The following sketch will show the arrangement in section. C is the core; BB, the ends of the wooden bobbin; F, is flange into which the core C is driven *very* tightly. A good way to keep the wires together at the other end is to tie them together and dip into melted shellac—glue will do—and, when this is hard, remove the string. The flange F is now fastened to one end of the bobbin by means of three screws. You will now find that the tube T will move over the core easily. This regulator is much greater than the ordinary regulator, if you do not want the trouble of bringing out the strengths by the wire. With mine, I can light up vacuum tubes and do everything that can be done with a small coil.—Electric Light.



[46207.]—**Weight of Cattle.**—The weight of cattle may be calculated by measurement in the following manner:—Measure the girth close behind the shoulder, and the length from the fore part of the shoulder-blade, along the back, to the bone at the tail, which is in a vertical line with the buttock, both measured in feet. Then multiply the square of the girth (in feet), by five times the length, and divide the product by 21, and the quotient is the weight (nearly) of the four quarters in imperial stones of 14lb. avoirdupois. For example: let us suppose that an animal is 5ft. in girth, and the length is $4\frac{1}{2}$ft.; ∴ 5ft. by 5ft. = 25, and $4\frac{1}{2}$ft. × 5 = $22\frac{1}{2}$; ∴ 25 × $22\frac{1}{2}$ ÷ 21 = 27 stones (nearly). In exceptionally fat cattle, however, the weight will be about 1-20th more, and those in a very lean state it will be about 1-20th less, than the weight obtained by the preceding rule.—A. J. D.

[46209.]— **Photographic.** — You can have flashed metal of any degree of colour in proportion to the thickness of the coloured metal on the surface of the glass used. Get the deep ruby as ordinarily sold, and you will be quite safe. You can buy flashed ruby from 1s. to 2s. per square foot; but I do not know the price of pot ruby, and I am not sure that I have seen any in sheets. It is rather too expensive to use for window-glass. I will give the instructions as to the dark-slide. Nobody seemed to require the instructions, or I would have given them. I am sorry to neglect anyone, but I endeavour to use the little time I can spare for the "E.M." for the benefit of the greatest number of querists or readers.—W. J. Lancaster.

[46211.]— **Wheatstone's Bridge.** — If the querist has got muddled with Ferguson's description (which he ought not to have done), I think he ought to clarify his perceptions by the directions, p. 168, of my book, which he appears to have at command. He may put his resistance to be measured in any one of the openings. As to the galvanometer, I can only say that if he alters the wires as to size and space fitted up, the readings I give will be utterly useless and incorrect. I cannot make the description more simple than that in my book, 90 turns of 20, 9 turns on each side of 18, connected as derived circuits to divide the current, 1 turn on each side in same way of copper strip. He can, if he likes, wind on as much 36 silk-covered as space admits outside of the strip, but its power will not bear much relation to the others, though it may be generally useful.—Sigma.

[46212.]—**Vegetable Black**—This substance, if packed in a leaky cask when freshly prepared, would condense the atmospheric gases on its surface, which, owing to the porous nature of the substance, is very large in proportion to its weight. In condensation the gases would give out a certain amount of heat, which, under favourable (or to you unfavourable) circumstances, might be sufficient to cause the ignition of some inflammable substance accidentally present, which by combining with the condensed oxygen, might liberate heat enough to cause the ignition of the vegetable black, which, when once started, would soon spread until the contents of the cask became red-hot. It is very unlikely that the heat liberated on condensation of the atmospheric oxygen would ever cause the ignition of the "black" directly, and even with a very inflammable impurity present that ignition would hardly ever occur.—J. M. Stocks.

[46212.] — **Vegetable Black.**—Fires occurring from the spontaneous ignition of vegetable black are very common, as the following paragraph, written by Superintendent Tozer, will show. Many porous substances, like fibres, when oily or greasy, are liable to self-ignition, especially during the summer after a continuance of dry warm weather. A sudden storm or a shower of rain appears to give life, as it were, to the parched-up matter, and a fire is the result. I have also noticed frequently the very reverse to occur after a continuance of wet weather. A few days sometimes are sufficient to set up active and rapid combustion, especially among sweepings in paint and oil-stores, consisting generally of wood-dust, dried vegetable and animal powder, colours more or less saturated with varnish, turpentine, oils, &c. This is one of the most common causes of fires in such stores. Several fires have occurred at which I have been present, when the damage done was confined within a cask of vegetable black. One occurred within our own workshop on a damp summer's night, through the carpenter on the previous afternoon dipping a wet paint can into the powder for the purpose of mixing some black paint. Ten hours afterwards the centre of the cask was found one mass of fire.—Thos. Marwood, Fireman, Chief Fire Office, Birmingham.

[46212.] — **Vegetable Black.** — Spontaneous ignition is not unfrequent in many large carriage factories, and builders' shops have been destroyed solely from this cause. So well is it known now, that various devices are adopted to obviate the chances of a disaster. The large firm of Wilkinson, Hayward, and Co., London, pack the lampblack in half-pound packets, done up in brown paper, and then packed in casks. To put it in printed paper would insure ignition, from the absorption of the oil in the printing-ink by the lampblack, generating gas which would soon ignite the soot or lampblack. One amongst many instances of well-attested cases of spontaneous ignition occurred at a large carriage-works at Grantham, in a shop far away from fire or the chance of a spark. The paint-shop was gradually illuminated on a mild summer's evening during daylight. It was noticed through the workshop-windows, and seen to be a tub of loose lampblack slowly consuming the cask. It was easily carried out on to the grass to finish its work. It was thought that, being near the grinding-paint-stone, some oil had been splashed into it, or an oily rag dropped into the lampblack. The secret was soon found out, by the pallet-knife being found amongst the ashes of the cask, having been carelessly dropped in with some wet paint on it; or even without any wet paint, the dry, oily paint which accumulates on the blade near the handle would be sufficient to cause ignition. It is not the large quantity of oil, but the small quantity, which is the cause of it. This is so well known, that some coachmakers, when they receive lampblack, put it into a sound cask and pour enough linseed-oil into it to saturate the whole. I caution workmen of the danger of oils near lampblack, and put the packets high up, out of the way of contact with oils. It would be well if lampblack casks had labels with a notice that minute particles of oil ignite lampblack in bulk.—J. Charles King.

[46213.]—**Measuring Steam.**—Why not find the amount of steam consumed in one stroke of "B.'s" engine or engines, and multiply that by the number of strokes made in a day or in one run. By fitting a counter to the engine a record of the number of revolutions could be kept, and an account taken daily or weekly, as might be found convenient. The pressure at which the steam is supplied would still have to be considered, and allowance made. This would, I believe, prove a better method than the one in use, and would tend to encourage economy. It would, nevertheless, be imperfect. Perhaps some of the other readers would kindly offer their opinion upon it. I am not aware of any form of meter for steam.—Ecosse.

[46213.]—**Measuring Steam.**—Seeing that the pressure of any given volume of steam indicates the energy or amount of work that B. can get out of it, it is fair that the price should be based on the pressure, and a fairer method of estimating its money-value cannot readily be conceived. To fix the price by volume would not be equitable. It would be a bad bargain for B. to have to pay for any stated volume of steam of 20lb. pressure the same price as if it had been of 40lb., and A. would have little inducement to supply the latter when he could get the same money for the former pressure with a less expenditure of fuel. If any encouragement to using the steam with economy is required, let an arrangement be come to, to pay only for the hours during which the engines have been actually at work.—Diamond.

[46214.]—**Stone-Lathe.**—No difficulty of any moment suggests itself. The way I would advise would be, if the mandril is provided with the usual three-speeded cone pulley, take it off, and get one cast from it, affixing to it core prints for the hole for shaft of overhead motion, said shaft's length being governed by the length of your bed (not given), so that you may be able to reach lever for throwing belt on to a fast or loose pulley, as required, and on which the belt from the fly-wheel works. I would have this overhead shaft, say, 1in. or $1\frac{1}{8}$in. diameter, according to its length, running in two standards bolted up to ceiling, about, say, 2ft. back from a perpendicular to the mandrel. You do not state the possible weight to be revolved in lathe. But I should advise a cast-iron wheel of about 5ft. diameter, belt pulley bolted to the spokes of this, with, say, two speeds, one of 2ft. diameter, the other, say, about 14in. or 16in., mounted upon suitable standards; wood upon end for bearings will answer well. Handle at each end of axle, "one up," when the other is "down."—J. J. A., Liverpool.

[46216.]—**Strength of Materials.**—I should be loth to rely upon calculations anent material and thickness of same in any man's model-made boiler, and have often given in these pages the best and easiest method of testing. Nevertheless, if "Barkis is willin" and "Eddy" is eulogistic, here we are again. Fill your boiler perfectly full of water, load your safety-valves with, say, double the pressure you ever mean to work it at, and place it on the fire, or, as I do, over a species of atmospheric gas-burner of my own design. The water soon expands and points out all (if any) leaks, and either bursts quietly or escapes at safety-valve.—J. J. A., Liverpool.

[46217.]—**Model Electric Engine.**—I should advise you to make one on the dynamo-electric principle, with the Siemens armature. You would get as much power from one weighing $3\frac{1}{2}$lb. as the one described some weeks back wound with 20lb. 14 wire. Will send photo. of one, and sketches, if editor is willing to insert with engravings.—George Tolman. [Please send.—Ed.]

[46217.]—**Model Electric Engine.**—You do not say about what size you would like to make engine. If you will say about what size you wish to make I will give you all instructions. I have lately made several simple motors that are capable of doing all sorts of light work, such as driving fret-saw or sewing-machine, and am now making one equally portable to probably drive a tricycle. If this succeeds, I shall have something to say about it shortly.—W. J. LANCASTER.

[46222.]—**Link-Motion.**—The length of link, from centre to centre of pins in eccentric rods, should be three times the travel of lever on rocking-shaft. This is not imperative; a little more would reduce the vibration, and consequently the wear and tear of the parts. A straight link will answer the purpose as well as a curved one.—ECOSSE.

[46223.]—**Electric Alarm.**—To MR. LANCASTER.—You can connect the bell to the clock very easily, and must get up to stop the bell ringing. Put bell in any convenient place, and couple bell to battery with one line, then carry another line from battery to clock and one from bell to clock. Now the contact maker shall be the simplest you can make, and the most successful. Go to the ironmonger's and purchase a hinge with long arms, say 1in. to 1½in. long, and about ⅜in. to ½in. wide, well work the knuckle until, when one half is upright, and the least move out of the perpendicular, it will fall down. Having done this, place it on a wooden base, one half of the hinge screwed down and attached to wire from battery; then put another piece of metal on same board, so that when the hinge falls down, it will drop on to this second piece of metal. Hinge ready for finger to move is shown thus—L; the upright leans against a pin just out of the perpendicular. Suppose, now, your finger just pushes it a little, then it falls on to opposite piece of metal thus, —⌐—, making contact the moment it touches. Of course, you must arrange hinge so that the minute-finger clears it. You will, I think, understand it in a moment, and will be able to apply it almost as quickly. Of course, the wire to bell is joined to the piece of metal on to which the hinge falls. You will have to get out of bed to stop bell ringing. The easiest way will be to keep a little wooden wedge to put under the hinge, then at night the hinge would be moved into position, piece of wood removed, and of course at 6 o'clock the bell would ring again.—W. J. LANCASTER.

[46224.]—**Silver Solution.**—Do not attempt the bright solution unless you are thoroughly master of the common one. It is always very troublesome, and requires to be kept in constant work to be of any good.—SIGMA.

[46224.]—**Silver Solution.**—The reason the articles are discoloured is through your putting carbon bisulph. direct into solution. Filter solution again, and if any carbon is at bottom remove it at once, and proceed as follows: Take a quart bottle, and into it pour 2oz. of carbon bisulph., and then fill up the bottle with a solution of cyanide (about 1lb. to gallon), after standing a day or two add a little each time you work solution.—ELECTRO.

[46224.]—**Silver Solution.**—I believe that Gore's "Electro-Metallurgy," 6s., first caused me to introduce a few drops of CS_2 into a plating solution. As I have not the book at present, I cannot say for what object the CS_2 was to be used, but I had an idea that it was to work wonders in some way. The result, however, was a dirty mess, which might be caused by the formation of Ag_2S as a black ppt. insoluble in everything the plating solution contained. Perhaps pure CS_2 would not give this ppt.; but I have never cared to try it, because I only keep a 4oz. bottleful of the solution, which was prepared three years since (by dissolving AgCy in KCy, and adding an excess of the latter) for illustrating electro-plating to students, and it works as well as ever—in fact, I have used it at three classes this week. For reliable information on this subject I should prefer the back-numbers of the ENGLISH MECHANIC before any books that I am acquainted with.—J. M. STOCKS.

[46226.]—**Gold Solution.**—For a small quantity of solution, like you say you use, you had better boil down to dryness, and then redissolve the residue in a weak solution of cyanide. After heating the solution, you do not get the desired colour, add a little more cyanide, and then if you fail, you have evidently some impurity in your solution, making it worthless; in that case, I shall feel great pleasure in giving you full instructions how to proceed to make a solution that will work satisfactorily; but try the remedy I have given first. You are not the first who has failed, and if you had read all the books published, you would still find that practice is better than reading. You had better continue reading "E. M." than any others.—ELECTRO.

[46229.]—**Transit of Venus and Earth's Distance from the Sun.**—It is intended with the coming Transit to arrive at some international agreement respecting the solar parallax, and, consequently the earth's distance from the sun. The present value of the parallax, 8·85″, is probably very nearly right; but astronomers generally favour the opinion of a smaller one, somewhere between 8·85″ and 8·80″. Taking 8·82″, which will correspond to a distance of 92,700,000 miles, Professor S. P. Langley is of opinion that astronomers in 1882 will not alter it by more than 0·01″, and as this angle is about equal to that filled by the apparent thickness of a hair seen at one mile distance, "E. J. B." can form some idea of the delicacy of the problem which has to be solved. Very little of the transit will be observed in this country. If we are favoured with a clear horizon at the time, we shall be able to observe the planet enter upon the sun's disc just before sunset, and then we shall lose both planet and sun together. Our American friends will be far more favourably placed; those in the United States and South America will not only be able to observe it directly after sunrise, but watch the whole phenomenon to its close.—A. MANOCK.

[46230.]—**Sensitised Paper.**—It will pay you much better to buy the paper ready prepared, than to attempt to make it. There are many things you can do, and some few that are much more expensive to manipulate than the finished article will cost you. This is the case with the gelatino-bromide paper, and I would certainly advise you not to attempt to make it. Still, if you have a desire to do so, let me know, and I will tell you what to do.—W. J. LANCASTER.

[46230.]—**Sensitised Paper.**—If "W. E. K." wishes to coat paper with gelatine bromide emulsion, he can do it by drawing paper rapidly over an emulsion kept warm in a flat dish. The emulsion should be kept nearly an inch in depth in the dish. Any good photographic paper can be used. The emulsion does not get weaker, the paper keeps well. "W. E. K." will find, however, that the paper he can buy ready coated is better than he can make on a small scale. It is more difficult to coat paper satisfactorily than glass plates.—H. G. M. CONYBEARE, Ingatestone.

[46231.]—**Cleaning Flower-Pots.**—There is no remedy for the efflorescence but cleaning; it is mainly lime and "salts" from the soil, dissolved by the water, which accounts for the fact that the pots receiving the least water have the least bloom. The remedy, if "G. H." objects to the efflorescence, is to use pots of glazed earthenware, which will not injure the plants, as is supposed in some quarters.—NUN. DOR.

[46235.]—**Reducing Balance-Spring with Acid.**—If "T." will follow my instructions, he will find it answer his purpose. Get a watch-glass nearly full of water, put four drops nitric acid in it, and put balance-spring in; let it stop in about ten seconds, take it out, put it in spirits of wine for about a minute to keep it from rusting; take it out, put it on balance, put roller on, put watch in beat, and you will find that the watch will lose instead of gain.—NICHOLLS.

[46238.]—**Turnstiles.**—You can easily make a registering apparatus to tell how many people have gone through the turnstile. If the stile allows four people to go through in one revolution, then it must have four depressions. The lever working into the depression will move a train of wheels up to 10,000, or more if you like, indications. You would get a good idea of the arrangement from a gas-meter: the train of wheels run along in tenths, the pinion revolving ten times for one revolution of next wheel. This would be the kind you would require. If the first wheel indicated 10 persons for one revolution, the next would be 100, then 1,000, 10,000, and so on up to any number.—W. J. LANCASTER.

[46240.]—**Legal.**—It is impossible to advise upon this question without having fuller details. But certainly the firm you employed could not be liable to their workman for an injury happening to him by the explosion of a steam-valve of your engine. As to whether you are responsible, everything would depend upon the evidence. The Employers' Liability Act is not concerned, because the man was not in your employ; but you would be liable at common law if the accident resulted through the defective or dangerous condition of your engine, or arose in any way by your fault, unless indeed the workman contributed to it by his own negligence.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[46242.]—**Patent Law.**—Certainly. The patentee grants a license to use his patent, and so long as he does not "assign" it—which must be registered at the Patent Office,—it remains his property, and he grants as many licenses as he pleases, either in consideration of lump sums, or of the payment of royalties.—NUN. DOR.

[46242.]—**Patent Law.**—A patentee can enter into an arrangement to receive a lump sum from any company for the use of his invention by the said company, without such action necessarily implying that he parts with all right to the patent. The patentee may sell his invention outright, or grant licenses. In the case stated he would simply be paid a lump sum for a license.—DIAMOND.

[46242.]—**Patent Law.**—If by the arrangement with the Railway Company the patent only gives them the right to manufacture for their own use, then he can undoubtedly make similar arrangements with other companies to do likewise. But if the question means that the patentee transfers the exclusive right of manufacture for a lump sum, then to give others such a right, would be a breach of contract. Presuming that the former is the right reading of this query, then the mere sale of the right of manufacture would not amount to a sale or assignment of the patent itself.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[46245.]—**G.E.R. No. 385.**—This was a four-coupled engine, and was formerly used for passenger traffic between Cambridge and London. It was designed by Mr. Sinclair, and rebuilt about 1876 or 1877 by Mr. Adams at Stratford. The bogie was added then.—G. C. M. HALL, Colchester.

[46246.]—**Sulphate of Copper.**—"Etcher" may readily convert his nitrate of copper into sulphate by adding excess of sulphuric acid, and evaporating in a porcelain basin until fumes of nitric acid cease to be evolved. The residue will be copper sulphate. It may be dissolved in hot water, and set to crystallise.—ANALYST.

[46247.]—**Photography.**—It is evident you are not working in the dark, and ought to know better. Now, then, tell me have you a dark ruby glass in the window of your dark room? If not, then light is the cause of fog. If you have time in developing to watch until the picture is seen through the back of plate, you have certainly not over-exposed them. I don't believe you have anything wrong besides too much light. Alter it, and you will soon succeed.—W. J. LANCASTER.

[46247.]—**Photography.**—If you are working with gelatine dry-plates, your trouble is probably fog. Are your dark slides perfectly light-tight, and what sort of light do you use to develop by? Are the edges of your plates, where protected from light by the plate carrier, clear and free from deposit? If the edges of the plates are clear glass, the fault may be due to over-exposure. One thickness of ruby and one of orange paper together over your window will give a perfectly safe light. I will try and help you further if you will send another query.—H. G. M. CONYBEARE.

[46248.]—**Amateur Dramatic Club.**—"A Fellow Workman" will find much useful information in a book written by an amateur performer of considerable experience. The title is "What shall we Act?" by M. E. James. Geo. Bell and Sons, London, 1882.—J. COLBY.

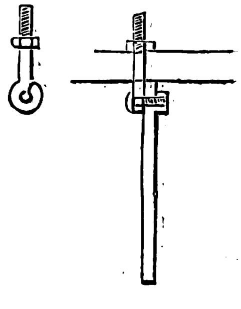
[46248.]—**Amateur Dramatic Club.**—Write to French, the theatrical publisher in the Strand, for his catalogue of acting plays. In it you will find a number of pieces suitable, with full particulars regarding scenes, number of characters, male and female, in each; also if past or present style of dress. He lends, for hire, the scenes, &c., required for many of them. Dresses, properties, and other requisites can be procured at any of the theatrical costumiers, who, on receipt of title of play, will supply you with every needful dress for acting same. Among the best costumiers may be named, May, Bow-street, Covent-garden; Nathan, Tichbourne-street, Haymarket; and Simmonds, King-street, Covent Garden. Wigs can be had from French or Clarkson, of Wellington-street. I might add that a most excellent manual, price 1s., is published by French on "Making-up," which by all means get, its hints being invaluable.—ARTHUR E. MORRIS.

[46250.]—**Fitting-up Battery.**—If you cannot go to the expense of clamps, better cast lead caps on the carbons, and solder them to small brass brackets, and screw them with wood-screws where you want them. You cannot solder to amalgamated zinc, as the solder amalgamates with the mercury. Should certainly use clamps in both cases.—GEORGE TOLMAN.

[46250.]—**Fitting-up Battery.**—Bend a piece of brass into this shape ⊓, then screw the carbon plate on to one side and the zinc plate on to the other side. You can tap the brass two holes on each side, and then drill holes in the zinc and carbon plates to correspond; then, with large-headed screws, fasten all together, and paint over with shellac varnish; screw the brass plate up against wooden carrier.—W. J. LANCASTER.

[46250.]—**Fitting-up Battery.**—Bend a piece of thick wire like Fig. 1, screw end, and fit nut, screw copper rivet, and fit nut, bore hole in C plate ½in. from centre of width and ¾in. from top edge, fix bent wire to C plate by screwed rivet. If zinc plates are thin, treat them in the same way; if thick, drill hole in end ½in. from centre of width, tap, and screw wire to fit. Bore holes in lifting-bar, which may be 2in. wide by 1in. thick, pass wires on plates through, and fix by nut, Fig. 2. All the wires from zinc plates must go through holes ½in. on one side of centre of width of bar, and all wires from C plates through holes ½in. on opposite side, so that the centre of width of plates is in centre of width of bar. You can connect the

FIG. 1, FIG. 2.



plates for various effects by wires between the lifting-bar and nut, terminal wires being fixed to the terminal plates in the same way.—J. M. STOCKS.

[46251.]—**Inhalation—Compound Oxygen.**—The article in question is probably an aqueous solution of hydrogen peroxide—a very unstable compound, readily decomposed into water and free oxygen on gently heating. It may be purchased at a moderate rate from any operative chemist. It is prepared by passing carbon dioxide through water holding finely-powdered barium dioxide in suspension, and filtering off the insoluble barium carbonate, or by adding barium dioxide to dilute hydrochloric acid, as long as it is dissolved. The solution in this case would contain barium chloride as a complementary product; but this would not interfere with its use as a source of free oxygen.—ANALYST.

[46251.]—**Inhalation—Compound Oxygen.**—Will "Tom" warm some of this substance in a test-tube, and insert a splinter of wood (which is just red-hot at the end) into the liberated gas. If the splinter bursts into flame, then moisten a piece of blotting-paper (white) with acetate of lead, expose paper to sulphuretted hydrogen (which turns it black), then put a drop of the American article on the paper. If the latter is turned white, buy a small quantity of hydrogen peroxide at 4s. 6d. per lb. in any large town, and see if that will produce the same curative effects as the substance you mention. You can prepare hydrogen peroxide by passing CO_2 through a mixture of BaO_2 and water for some time; then filter, when solution contains the hydrogen peroxide. Report results.—J. M. STOCKS.

[46251.]—**Inhalation—Compound Oxygen.**—The liquid is only a solution of hydroxyl or hydrogen dioxide (H_2O_2), often called oxygenated water. It contains just twice as much oxygen as ordinary water, hence it is sometimes called peroxide of hydrogen. It may be prepared by dissolving baric dioxide in dilute hydrochloric acid; precipitating the barium as sulphate, by means of sulphuric acid. The extra atom from the dioxide combines with the water, instead of being given off in the gaseous form. Fresh baric dioxide is again added and precipitated as above, until the solution is strong enough. These operations require performing carefully. Another manner by which it may be prepared is to pass a current of carbonic dioxide gas through water holding baric dioxide in suspension. The solution which is made by either of the foregoing methods, can be further concentrated under an air-pump, until it becomes a thick syrupy liquid, totally distinct from water. Very little rise of temperature causes the oxygen to be evolved with effervescence. A solution, containing ten volumes of the gas, can be obtained from the chemical dealer's, at about 4s. 6d. per lb. Without you are used to chemical manipulation, I should advise you to buy, instead of endeavouring to make it yourself.—ARTHUR E. MORRIS.

[46252.]—**Electric Bells.**—The following will, perhaps, suit; for although the resistances are not quite the same in each coil, you will find them most suitable for electric bells for ordinary purposes. Each bobbin must be filled level with size wire given.

	Bobbins.		Silk	Core.	Armature.
Bells.	Long.	Diam.	Wire.	Diam.	Square.
in.	in.	in.		in.	in.
2	1¼	⅝	30	¼	¼
2½	1½	¾	28	5-16	5-16
3	1¾	⅞	26	⅜	⅜
3½	2	1	24	7-16	7-16
4	2¼	1¼	22	½	½

—GEORGE TOLMAN.

[46252.]—**Electric Bells.**—A simple rule to remember will give you all the information you require as to size of electro-magnet for each size belt. Let the cores be one-half the length of diameter of bell, and their diameters one-fourth their length. Thus, for 2in. belt the cores would be 1in. long and ¼in. diameter; then the bobbins must contain a depth of wire equal to diameter of core. You can use 26-wire for small bells, and up to 18 for large bells.—W. J. LANCASTER.

[46253.] — **Spin - Wheels.**—Soak well with paraffin oil, and they will drive off easily.—J. J. A., Liverpool.

[46255.]—**Steel Stencil-Plates.** — Any ironmonger or tinman should be able to get you such sheets of the dimensions named, in steel, from the tin-plate manufacturers.—DIAMOND.

[46255.]—**Steel Stencil-Plates.**—I would go to a tenon-saw maker where the steel could be procured. Make it red hot (being careful not to burn in any part); when red, cover up in sawdust. This will leave it soft as the finest quality of iron, with no nasty pins in its texture; cut desired letters, &c., and then heat over a "charcoal fire." Hold it out in the open to cool, then stand at ease.—J. J. A., Liverpool.

[46256.]—**Poor-Rates.**—The rent of a house or premises has nothing to do with its rating, except as some evidence of value. Business premises are assessed according to the class to which they belong, as shops, warehouses, or mills, and if there be machinery upon them, that is considered in the valuation. It is obvious that the rent paid under a lease would often be no indication of the true annual value. If "H. H." thinks the rating too high, he can appeal within the time allowed from the date of the assessment.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[46257.]—**Astronomical.**—Of course, a finder of almost the lowest power will enable you to pick up Uranus. It can be seen with the naked eye by many people, but is very difficult to the majority of observers as a naked-eye object. His angular diameter is, as you know, 4″, and never differs to any appreciable extent. This gives him about the same brilliancy as a sixth to seventh magnitude star.—W. J. LANCASTER.

[46258.]—**Discolouration of Bricks.**—Though in the business myself, I have never heard of any remedy for the white efflorescence which occasionally appears in red bricks. It is due to the presence of some salt, usually potash or soda, in the material, which works to the surface of the brick, and shows as a white scale. The only cure I know of is time. When the salt, whatever it may be, has all worked out and been washed away, the discolouration will cease. In the case of a house, it might be washed off with a hose, repeated till no more appears. My chimney "whitened" in places for months after it was built, but it wore off by degrees. Bricks that have been burnt in a Hofman kiln occasionally show a whitish colour in the ends where they have received the steam from the adjoining bricks; but that, too, wears off with time and weather. The same remarks apply to flower-pot (query 46231). It is a peculiarity of the material, which, as far as I know, nothing but time will get rid of. In flower-pots, perhaps the supply of salt is kept up from the earth used in them.—TREADLE.

[46259.]—**Piston Speed.**—To obtain piston speed multiply the stroke in inches by the speed in miles per hour, and by 56. Finally, divide this product by the diameter of driving-wheel in inches. The result will be the speed of piston in feet per minute. Applying this to your example, 26 × 60 × 56 / 84 = 1040ft. per minute.—ED. GOBERT, B.Sc. (Nottingham).

[46259.]—**Piston Speed of Locomotives.**—A 7ft. wheel is as near as possible 22ft. in circumference (7 by 3·14159); a mile is 5,280ft.; therefore, a 7ft. wheel makes 5280 / 22 = 240 revolutions per mile, or per minute, when speed is sixty miles per hour. With a stroke of 26in. the piston must travel 52in., that is 4·33ft. at each revolution; therefore, piston speed will be 240 × 4⅓ = 1040ft. per minute, a very high piston speed. The engine should, I think, have a larger driving-wheel or a shorter stroke. I have made for myself a small table, by which piston speed can always be calculated in a few moments.—L. G. B.

[46259.]—**Piston Speed of Locomotives.**—Rule: Multiply the number of revolutions of the driving-wheels per minute by twice the length of stroke in feet and fractions of a foot. The result is the piston speed in feet per minute. Thus, in the instance given, train is going 60 miles per hour—that is, 60 × 5280 / 60 feet per minute. Wheels, in one revolution, go 7 × 3·1416ft. Therefore, the wheels revolve 60 × 5280 / 60 × 7 × 3·1416 = 240 times in a minute. At each revolution, piston travels 26 × 2 = 52in. = 4⅓ft. ∴ piston speed is 240 × 4⅓ = 1040ft. per minute. The diameter of the cylinder has nothing to do with the piston speed.—GUIDE-YOKE.

[46259.]—**Piston Speed of Locomotives.**—The following is a simple rule for finding the piston speed. Speed of train in feet per minute × stroke in feet × 2 / circumference of driving-wheel = piston speed. For example: 60 miles per hour = 1 mile per minute = 5,280ft. per minute; stroke = 26in. or 2 1-6ft., circumference of driving-wheel = say, 22ft. Then, 5,280 × 2 1-6 × 2 / 22 = 1,040ft. per minute. The multiplier 2 is used, because each revolution of the driving-wheel equals two strokes of the piston. In this case the piston travels through 52in. or 4ft. 4in. for every revolution of the driving-wheel.—ECOSSE.

[46261.]—**Brakes.**—Holbech's new self-acting continuous brake acts by the momentum of each carriage, each one being independent of the other, and, under present circumstances, when the driver pulls over his lever all automatic arms are in position to act on brakes being applied on engine or front carriage, as if that brake is sufficiently powerful to put the required pressure on the next carriage those brakes are applied, and so on to the end of the train, be there one or a hundred. The brakes are applicable to all carriages that run on metals, either railways, tramways, or mines, as 20 to 50lb. springs per ton will effectually apply the automatic arms, and also the brakes, whenever the momentum exceeds the pressure at which the brakes are set to act, and each carriage will relieve its brakes when the momentum falls below that pressure, and can so be set by a pin by the superintendent of the carriage department. The arms can be thrown out of action by the guard; but, should the train be divided by any means—as failure of draw-bars, breaking of coupling-chains, or any other cause—a breakaway apparatus is provided, which locks the wheels of parted carriages in a moment, and applies continuous brake to left portion of train that also forms an efficient hand-brake for station or sidings. The great utility of this brake is first no steam, air, or vacuum cylinders, tubes, taps, or couplings are required; no thought of applying brakes is required when wanted to stop, as that is done before trains leave a station; also, should one or more carriages have their brakes deranged, they do not affect the remainder; each carriage will actuate its own brakes in any train, and almost any brakes may be used by my apparatus without interfering with their usual working; be they Westinghouse, steam, or vacuum; no extra fitting required on engine, so that many accidents might have been prevented had this invention been placed under the others to act where the scientific brakes are not understood, or not in working order. My hand-brake will lock engine-tender or guard's van in two or three turns of their wheels, when lever is pulled hard over. Models can be inspected in Leicester by appointment or application to patentee.—W. B. HOLBECH, Enderby, Leicester.

[46262.]—**Battery.**—You cannot beat the Fuller cell for fair constancy, but you cannot have power and constancy. Let me know the purpose for which you require the cells, and I will do my best to advise you.—W. J. LANCASTER.

[46262.]—**Battery.**—You cannot have a better one than the Bunsen; but you must charge the porous cell with nitric acid, or dipping aquafortis. It is tomfoolery to use the bichromate solution, unless you are working through a great resistance.—GEORGE TOLMAN.

[46262.]—**Storage Batteries.**—The force of Sutton's is considerably below the Planté; and I must say I have never yet seen one of these with a force of 2·5 volts. I am afraid Mr. Hezmalhalch will not get his questions answered. They would involve a complete treatise on electric lighting.—SIGMA.

[46267.]—**Piano Pins.**—These pins are not tapped with any thread, being simply filed slightly taper at points, and depending for their hold (like the violin pegs) upon the friction induced by driving them into a smaller hole than their own diameter, in hard beech. When from carelessness in not pressing home, or bad stringing, the pin protrudes from its normal nucleus, simply drive it in again with the hammer head, to be found upon any proper tuning key; but slack up the strain on wire before you hit.—J. J. A., Liverpool.

[46268.]—**Electro-Gilding.**—If your solution is one of double cyanide of gold, you have only to add a little free cyanide; have a stronger current from battery, and use solution at nearly boiling-point.—ELECTRO.

[46271.]—**Secondary Current in one Direction.**—The current produced in an induction coil is so feeble in quantity, that it could not be made to do any mechanical work, unless it was a very powerful coil, with large battery power, and specially constructed bells of high resistance. It would be just possible to charge a small secondary battery for very occasional use, but would simply cost about a dozen or two times as much as a common battery.—SIGMA.

[46272.]—**Legal.**—This is a very complex question which I cannot answer conclusively without knowing more. If the occupier has been in adverse possession of the office and buildings for over twenty years, then he has acquired a legal right to them; but if that occupation has been by the license or permission of the owner, that right would not accrue. If the statute of limitation applies, and the occupier has had over 20 years' adverse possession, then he cannot be disturbed or made to pay any rent. But should this not be so, and of this I cannot be certain without knowing more clearly all the facts, then the occupier, if no rent has been fixed, would be liable to pay a reasonable sum for the use and occupation (though not for more than six years past) while being a tenant at will. He could be served with a notice to quit at any moment.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall, E.C.

[46288.]—**Oval Lathe.**—Does "Oval" want to turn holes which are "oval," or which are elliptic? An "oval" is smaller at one end than the other, like the long section of an egg, from which, indeed ("ovum," an egg), the word is derived. Many people vulgarly call an ellipse chuck an oval chuck, whereas the ellipse chuck does not produce an oval but only an ellipse. A contrivance by Goyen, modifying the action of the ellipse chuck, is said by its author to turn ovals; but one gentleman, who had bought it, could not succeed, and when I tried it I saw no way in which it could be made to turn ovals. This was in the absence of instructions as to its use by Mr. Goyen. Other people call the ellipse chuck an "elliptic chuck," as if the chuck were itself elliptic, which, of course, it is not. Does "Oval" want to make holes which are oval, *i.e.*, egg-shaped and smaller at one end than at the other, or elliptic, *i.e.*, dish-shaped and alike at both ends?—J. E.

[46290.]—**Brass Casting.**—To insure against honeycomb, use new materials in the composition of the metal for your brasses. I have noticed that when old scrap is used, honeycomb almost invariably appears in the castings.—ECOSSE.

[46290.]—**Brass Casting.**—This may arise from pouring the brass when too hot, the mould not being dried enough, or not being sufficiently pricked to vent it. Brass-casting (like most occupations) requires experience, and a rational use of the reasoning powers of the pussons so situated.—J. J. A., Liverpool.

[46290.]—**Brass Casting.**—Your sand should be mixed well and often. Be careful when ramming, use the bellows freely, and if the brasses are large, vent them; but in all cases where sound castings are required, use a riser to your mould. This will bring off all the air, together with all the grit, and save you a deal of inconvenience when fitting them up.—PATTERN-MAKER.

[46292.]—**Dutertre's Gilding Solution.**—I am not acquainted with the formula for this solution; but perhaps the following, taken from a back number of the *Chemical News*, will answer the purpose. Dissolve 1 gram of fine gold in aqua regia, concentrate the solution by evaporation until it is the colour of ox-blood. Add half-litre of hot distilled water, in which four grams of potassium cyanide have been dissolved. Stir with a glass rod and filter. To gild with this solution, it is heated a little above lukewarmness, and the articles to be gilt are immersed in it and supported upon a piece of clean zinc.—ANALYST.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

The coal-tar or aniline dyes differ but in their molecules, and the quantities of hydrogen and oxygen. Water furnishes these gases by electrolysis, and M. Goppelsruder, of Bale, has submitted water holding certain colouring material in solution to an electric current, and has obtained various dyes.

QUERIES.

[46293.]—**Electro-Motor.**—My thanks are due to Mr. Lancaster for the very clear instructions along with drawings which he has so kindly given in answer to my query addressed to him, "Re Electro-Motor for Revolving Vacuum Tubes." I have made one exactly in accordance with the instructions given, but I do not get the required speed. It revolves very quickly indeed; but I should have liked it to have run at a very high speed, sufficiently so that when a tube is revolving it would produce the appearance of a catherine wheel, that is, it should produce the appearance of an unbroken circle of light. Would Mr. Lancaster kindly assist me? I made the electro-magnet exactly in accordance with his instructions given in No. 872, p. 336—and this works well. It has a very powerful attraction; the brass wheel is tinned, and will probably weigh ½lb.; the six armatures are as described, and ⅛in. thick; the commutator I have arranged to make contact when the cores are midway between the iron armatures, and contact broken just before the armature is over the centre of the magnet cores. Have I wound the magnet properly? I have wound both cores in the same direction—i.e., as if it were a straight bar, and then bent, having the same lengths of wire silk-covered on both limbs. I shall be very thankful to Mr. Lancaster for any information he will kindly give. I notice with pleasure that Mr. L. has the first part of his paper on the Rhumkorff induction coil finished. Would Mr. Lancaster kindly supplement his paper by stating the various quantities, sizes, and weights of materials for making coils of various sizes? Myself, I should very much like to make a 3in. coil, and shall certainly attempt to follow Mr. Lancaster's instructions, being so pleased with the success I have met so far, as others might only wish to make a 1in., and so on.—A. A.

[46294.]—**To "Sigma."**—The article on electricity in the *Encyclopædia Britannica* suggests the use of metallic sulphides in the construction of thermo-electric batteries, and refers to the works of Wiedeman for details. I have no opportunity of consulting the work. No doubt "Sigma" will have some notes on the subject, and would kindly suggest the best sulphides for use, and any incidental information that would assist me in the construction of a thermo-electric battery.—T. S.

[46295.]—**Paralysis.**—Will Dr. Edmunds and others kindly give their opinions on this case?—A friend of mine who is suffering from paralysis of the legs, and has been under treatment of several medical men, and tried almost every known remedy to regain his locomotive powers, now thinks that if a stationary machine were constructed, having cranks and pedals to fix to the boots, and worked by levers with the hands so as to give an action to the legs similar to walking, and take an hour's exercise daily in his room on this machine, it would tend to the recovery of his natural powers. My friend now rides a 50in. invalid's tricycle, Bayliss, Thomas, and Co.'s, worked by hand-levers, from which the idea is taken. No doubt there are many others suffering in the same way, who would be glad to know of something for their relief.—C. R. B.

[46296.]—**Harmonium or Organ.**—Through the kind help given in your paper by "Saul Rymea" and "Elève," I was enabled to build a two-row American organ about three years ago, with which I was much pleased. Now as past success makes bold for future endeavour, I wish to enlarge to a four row, one manual, using the same case, reeds, stops, and briefly all that is possible to be used, to save expense. Good-hearted "Saul."—Shall I make it pressure harmonium or suction American? Would the effect of American boards turned upside down with pressure-bellows and pallets, harmonium fashion outside, be satisfactory? In either case I am not clear as to how to make the pallet action for four rows. How is it done on the harmonium? In this four row I want variety and pure, pipe-like quality of tone. Advice will not be lost on one who feels grateful for past help.—BETA.

[46297.]—**To Mr. Lancaster.**—Can you tell me any rule by which I may ascertain the different thicknesses of wire on an electro-magnet, and an armature to revolve within it? I have two Siemens armatures wrapped with No. 18, and wish to construct two electro-motors, one on Grisćom's principle, and the other on Trouvé's; but hitherto have been unable to find out the thickness of wire for the magnets. If it depends on resistance, is there no way of measuring that without a resistance box; and finally, how is the amount of wire found, supposing the space it has to occupy, when wound, be known? It seems a very inaccurate way to treat it as solid copper weighing ·3225lb. per cubic inch. An answer will greatly oblige—CLÔTURE.

[46298.]—**Glycerine.**—Lately this valuable article has advanced so enormously in price that I am told soapmakers are now extracting it from their waste products. Will Mr. Allen or some other kind reader inform me the best means to adopt to try it on a large scale, and also state what the chief impurities are in commercial glycerine, with the best analytical method of detecting them?—INQUISITIVE.

[46299.]—**Precession of the Equinox.**—Will some of your numerous correspondents kindly inform me when the Sun first entered the constellation Pisces at the Vernal Equinox? In all the books on Astronomy I have yet seen, this fact is stated: that the Sun is no longer in Aries on the 25th of March; but none of them say when the change from Aries to Pisces took place.—ASTROLOGOS.

[46300.]—**Broken Drills.**—How can drills be got out of a brass plate 1¼in. thick? They are broken off about half-way through. The drills are "Morse twist" size 30, and the holes in which they are broken are drilled 6 to the inch (that is 36 to the square inch), so that they are quite close together. Can they be dissolved out by an acid that will attack the steel without touching the brass?—C. T.

[46301.]—**To "Sunlight."**—Thanks very much for answering my last query; but it is as I expected. If not troubling you, will you be kind enough to give description of boiler to suit engine ¾in. bore, one that will stand, say, 50 to 70lb. per sq. in.? and form of boiler. Would the cylinder stand, say, about 45lb. pressure? The covers are fastened with six screws at each end.—C. HORACE PHILLIPS.

[46302.]—**L. and S. W. R. Engines.**—Can "Clyde," or any other correspondent, kindly give me principal dimensions of this company's engine, Wildfire, No. 77, where built, and date?—F. G.

[46303.]—**Medical Coil.**—To MR. LANCASTER.—Kindly explain the manner in which a coil should be joined up, made with No. 18 wire for primary, and No. 36 for secondary with contact-breaker at end of coil? The reply you asked me to refer to in "E. M." of 17th ult., is in reference to a coil on a different principle from the above. Sorry for again troubling you.—JAS. MAIN, Aberdeen.

[46304.]—**Hardening Brass Wire.**—Will someone kindly inform me of a way to harden brass wire which has been made red-hot? I find it bends far more easily after being heated; but it is of no use as a spring without being elastic.—NORTHUMBRIA.

[46305.]—**Blowing Engines.**—Can any correspondent give me the following information regarding blowing engines?—Are they suitable for getting blast to a large number of smiths' fires? If they are, what size would be necessary for working, say, 50 heavy work fires? If anyone can give this information, along with particulars of construction and method of calculating the power of blast engines, it will be greatly esteemed.—CLARE.

[46306.]—**Telephone v. Bell.**—I am anxious for information with regard to the relative advatages obtained by using for telephone calls magneto-electric bells as compared with those obtained by the use of the ordinary electro-magnetic bells and Leclanché battery. I am at present arranging telephonic communication between some 24 different parts of a large building, and am anxious, if possible, to do away with the necessity of attending to 25 separate batteries. The points upon which I more especially wish to be informed are as follows:—1. Does the magneto-electric bell easily get out of order? 2. If I use a magneto-electric bell, is it necessary for me to have a battery of one or more cells at both ends of the line, Crossley's transmitters being used? 3. Is any special form of indicator required with the magneto-electric bell or will any of the ordinary forms do? 4. Should I be able to ring two bells at the same time in different places with the same facility as in the case of the ordinary electric bell? 5. Would the sound produced by a magneto-electric bell, such as ordinarily manufactured, be sufficient to call attention in a noisy workshop? 6. What is the average time during which the ordinary Leclanché cell will remain effective if not used more than 10 or 12 times a day for periods of, say, 5 or 10 minutes at a time, supposing it to be duly attended to? In short, for the use of servants and workmen little accustomed to use delicate instruments, would the magneto-electric system be as economical and serviceable as the ordinary electric bell for calling attention to the telephone; and would it be as easily made serviceable to meet the requirements of a large institution?—YEKNAS.

[46307.]—**Barrow.**—Will any of our kind readers help me with a few suggestions for making a light and inexpensive truck or barrow for carrying, say, pianos, &c.? I have a pair of wheels, axle, and springs. The wheels are 3ft. 6in. high; axle 3ft. 3in. between boxes; now I want the body. Any suggestions.—AMATEUR WHEELWRIGHT.

[46308.]—**Telescope.**—To MR. LANCASTER.—I have a first rate opera-glass, the lenses of which I should like to make an astronomical telescope. The lenses are achromatic plano-convex of 2in. dia., and, as near as I can measure them, of 3½in. radius. If you would tell me what additional lenses I should require, and how to find their distances apart, &c., you would greatly oblige me.—CROTCHET.

[46309.]—**Filterer.**—I have a water-tank sunk in the ground, and supplied with the rain-water from the roof of the house. There is a filter in connection with it, through which the water has to flow previous to entering the tank. The said filter contains about two tons of ordinary river-sand. Could anyone tell me if rain-water filtered in this way is fit for domestic purposes, or of any better material with which to charge the filter to make the water fit for such purposes?—GEORGE HUTCHINSON.

[46310.]—**Water Supply.**—Would it be practical to get a siphon to work with 1ft. of fall through a ½in. pipe half a mile long, the said pipe having to pass over a hill about 20ft. high? Or would it be better to cut through the hill to get the fall?—G. HUTCHINSON.

[46311.]—**Horizontal Engine.**—What should be bore of cylinder for engine to drive a 4in. centre lathe; also boiler and slide-rest?—SCRIB.

[46312.]—**Repairing Cylinder Face.**—Having a traction engine with cylinder and valve-faces roughly cut and worn, I wish to be informed the best way to get cylinder face up, it being boxed in.—HIGH PEAK RANGER.

[46313.]—**Roof for a Lean-to Hot-house.**—I wish to put a new glass roof and glass ends on an old hot-house of the following dimensions:—Height at back 9ft.; breadth at base, 12½ft.; slope of roof (back to front), 15½ft.; length, 21ft. I am informed that the cheapest plan is to put up rafters and glaze them when in position, leaving the ventilation to be managed by openings in the front and back walls. This I can easily do, as my walls are of brick. What size rafters should I use to carry 21oz. horticultural glass? How should the ends be constructed—should they be stronger than the sloping portion (my old one was blown down in a very heavy gale)? What size of glass, and what kind of timber is best? How should the latter be prepared for glazing and painting; what allowance should be made for expansion of glass and wood by weather? Wishing to do the carpentry and glazing myself, I should feel much obliged to anyone who will kindly give me any information on the subject.—MUSCATEL.

[46314.]—**Closet Cistern.**—Will some of "ours" explain the cause of the water coming down supply-pipe when cistern is three-parts full to water-closet when wind is rough? Is it necessary to have an air-pipe in the ᑌ-trap? It has worked some years without. Also, how can I put a new leather on valve in cistern?—does the brass pivot unscrew?—CLOSET.

[46315.] —**Ethoxo Limelight.**— Would "Sunlight" kindly tell me what alteration I would need to make on my mixed gas-jets to use them with the above light? Also, what is the size of the hydrogen generator, and is it in the form of a wash-bottle? My lanterns are a pair of Sciopticons, by Wood, London; but I seldom use the lamps. Any information on the above light would be greatly valued by—EXHIBITOR.

[46316.]—**Continuous Brakes on L. & S.W.R.** —Could any correspondent tell me if it is true that the L. & S.W.R. are going to adopt Smith's vacuum brake? I have noticed lately on one or two four-coupled tank engines belonging to that company, two brake-handles close together, one being for a steam brake, which is on the right hand side of the engine; what is the other handle for above the regulator? Is it for Smith's vacuum? If so, why is there a steam brake for the engine-wheels? There was a hose connecting-pipe at either end of the engine. Many thanks to "Centaur" and "Driver" for their answers to query 45712.—BRAKE-BLOCK.

[46317.]—**Ferns.**—Will someone be kind enough to inform me how to deposit copper on ferns? I have tried, by coating with plumbago, but the frond has swollen in the water, and thrown off the plumbago, and no deposit has taken place.—SINGLE CELL.

[46318.]—**Protecting Steam-Pipes.**—I am going to run a steam pipe 1in. dia. under ground for 500ft. for steam-heating; pressure of steam, 50lb. Would someone who has had some experience, please say how I can protect it so as to have as little condensation as possible? The ground here is frozen from 2 to 3ft. in the winter.—CANADIAN SUBSCRIBER.

[46319.]—**Engineering.**—Having a large quantity of stone to bring from a line to my work, a distance of 400 yards, I should like to fix a drum and tramway to make the loaded waggon draw the empty one back. Will some of your correspondents kindly inform me if this is practicable with a fall of 1 in 10, and where I could see a similar apparatus at work?—ENQUIRER.

[46320.]—**Motor.**—I have a machine that requires 28lb. weight attached to a handle to move it. What I should like to do is to obtain a motor to work it, which must be of small size. Therefore, I could reduce the power by spur gearing 5 to 1 or 4 to 1, which would, in the former case (if I am correct), reduce the power required to move the machine to about 5½lb. weight, but would necessitate a speed of 170 revolutions per minute. In the latter case the weight would be reduced to 7lb., and speed 136 revolutions. The machine is not a fixture, and will be required to work in various places. Could "Sunlight," or any kind reader, suggest something likely to suit? and oblige—POOR PETER.

[46321.]—**Tipping Clay Tobacco-Pipes.**—Can anyone inform me how tobacco-pipes are enamelled or glazed at the tips to prevent them sticking to the lips? Some are mounted with sealing-wax, which comes off when smoking.—TOBAC.

[46322.]—**Electric Sign.**—Will some reader of the "E. M." be kind enough to supply the necessary information to enable me to make a small electric sign? The letters of which would be composed of circular discs, bright. Or cost of one of one of seven 5in. letters?—GIBSON.

[46323.]—**Pumping by Steam.**—Will "Sunlight" inform me the best way to pump water by steam to supply a boiler? The well is 200 yards from engine—8 h.p. We have to pump the water at present by manual labour, which is a lot of trouble. I do not want to go to a lot of expense.—AMATEUR.

[46324.]—**Shuttle Tongue for Paper Tubes.**—Can any reader give me any information of the best sort of shuttle tongue for paper tubes? The ordinary shuttle tongues pull them out of shape, and cause the weft to break when the cop is half woven off.—BEDA.

[46325.]—**Intensity Coil.**—1. What is the relation between the coil and the cell-power that may be applied to it, so that one may know how to get maximum effects without risk to the coil? 2. In purchasing a coil for ordinary experiments, such as illuminating full-sized vacuum tubes; raising platinum wire to white heat; exploding gunpowder, &c., what qualities ought one to look out for? 3. Why is the ordinary sulphide of calcium not phosphorescent?—VOLVOX.

[46326.]—**Helical Epicycloids.**—In Vol. III. of the Amateur Mechanical Society, Mr. Burnaby gives a description of an instrument for helical epicycloids, and gives drawings and curves produced by it. It is very interesting. I should much like to construct such a machine. I have essayed making full-sized working drawings, but am not satisfied with them. To make all plain, I should like good elevations of the complete machine from three points of view. Photographs would probably answer if lettered, and a sectional drawing added. A friend, who was a member of the Society, lent me the first three volumes, but has no more of them. Nobody I know, knows whether a fourth volume has been published. If anything further has been written regarding this machine by Mr. Burnaby, I am sure many, besides myself, would be gratified by seeing in your pages what I ask for.—RAMADEEN.

[46327.] —**Steam Launch.**— In constructing a launch of iron 30ft. long, what beam and depth from deck to keelson would be requisite; and in what manner are the ribs set out? Or would any reader of your valuable paper supply me with working drawings?—DOX.

[46328.] —**Lodger.**—If a distraint is made for rent in a house where apartments by the week or month are let to temporary lodgers, are the belongings of such lodgers liable to seizure?—O.

[46329.] —**Chromate of Calcium.**— Will any chemical reader tell me how to make chromate of calcium?—W. T.

[46330.]—**Cream Separators.**—Could any reader give a description of Paterson's cream separator, as used in the Aylesbury Co.'s premises; also the Dairy Supply Co.?—A. B. D.

[46331.]—**Flageolet.**—I have a flageolet which, when I got it, would not play the C unless I hardly blew at all; but played, instead, the upper B. This, I thought, was because the wind did not strike fair on the edge of the whistle; so I took a little bit off the piece inside to make the wind strike lower down—but that made matters worse. It now plays the B only when I do not want it, and the C not at all. Will someone tell me the cause of this, and what I must do to set it right?—A MUSICAL CHIP.

[46332.]—**Electrical Resistance.**—Will some subscriber tell me the name of some liquids which offer a high resistance to the electric current? Also the method and instruments that are used to find the resistance of a circuit?—INQUIRER.

[46333.]—**Gregorian or Cassegrain.**—I have an old-fashioned Gregorian telescope by Dollond, on excellent stand. The mirrors are broken, and I wish to replace them by silvered glass ones, ground to spherical curves. I shall be very glad if one of our optical friends will tell me whether Cassegrain's or Gregory's construction gives least distortion? Also the best ratio for the focal lengths? The diameters must be 4in. and 1in. respectively. Is the distortion in these telescopes greater than in a Newtonian of equivalent focal length? Of course, I mean in a Newtonian with a spherical mirror.—G. L. E.

[46334.]—**Gas Purifying.**—I have a small gas-works (gasometer having a capacity of 6,000 c. ft.), recently erected by a first-rate maker, but am not successful in purifying the gas. I wish to know the proper modes of purification, and also the tests required—both for quality of light and purity of gas. I should also be glad to know the best kind of coal to use. The works are in Devonshire.—ROSICRUCIAN.

[46335.]—**To Mr. Lancaster.**—Some time since, you kindly replied to a question concerning the method of using permanganate of potash, put by me. If if be not asking too much, I would request an answer to the following:—I know that cottons and linens can be disinfected by permanganate, by steeping them in it overnight; but how should flannels (which are not usually steeped in cold water) be treated? Would not hot water hasten the action too much?—HOUSEKEEPER.

[46336.] — **Telephone Circuits and Call.** — Given a line and a return wire between two stations, and that each station is provided with a bell, a push, and a battery: a description, with diagram, is asked for, of proper arrangement of wires, so as to use the bell as a call, and then telephones at either station. Return wire is not insulated. Also, how, in foregoing query, to add a microphone to either or both stations?—MEME.

[46337.]—**Steam Launch.**—To "SUNLIGHT."—I intend putting a 5in. bore by 6in. stroke engine into a ship cutter 25ft. long and 6ft. beam. I have a propeller 2ft. 3in. diameter by 3ft. 6in. pitch. I wish to get in a cross-tube boiler or a vertical boiler with vertical tubes. The launch is for salt water. Will "Sunlight" say what size I will require, how much heating surface? Would a vertical boiler do, 2ft. 6in. diameter by 3ft. high, heating surface of firebox 12ft. 6in., and two 4in. cross-tubes, heating surface 4ft.; total, 16ft. 6in. Regarding the exhaust, I hope to condense same by series of pipes along the keel. Any further information will oblige—STEAMER.

[46338.]—**Sulphide of Calcium.**—Would some of our readers kindly inform me how to make this? I have tried heating sulphur and lime, but cannot succeed. Must the crucible be made airtight, or are there any particular proportions?—F. R.

[46339.]—**Dynamo Machines.**—Is it possible to make a small one, say for two 20-candle lamps? If so, any information as to construction would greatly oblige—F. B.

[46340.]—**Painting on Silk and Satin.**—I have painted on both these fabrics with oils and water-colours, but in both cases have found the paint to crack very shortly after completion. I should be much obliged to any correspondent who would tell me how this may be prevented.—LENT LILY.

[46341.]—**Nickel-Plating.**—During the last three years we have had a number of formula for solutions given; but at the present time nickel-plating appears to be done much better than heretofore. Will any practical subscriber of "ours" kindly inform me—1. The best working solution? 2. Power of battery. 3. Surface of anode (pure nickel) to be exposed to the surface to be plated. 4. Any preparation for steel. Following several formulæ in "ours," I get either a rough deposit or one that strips off steel in small pieces.—W. S.

[46342.]—**Estimation of $S'H_2$ and CO_2.**—Will "Analyst" or W. Duff kindly give a description of process for estimating the quantities of SH_2 and CO_2 that are driven off gas-liquor by boiling with lime?—L. D

[46343.]—**Smith's Fan.**—Will J. Perry kindly give me the size and all information concerning same as offered, as I want to make one to blow my fire instead of bellows? I have some chains taken from a Green's mowing machine—could I use them to work up the speed on same?—ALBERT HALL, Smith.

[46344.]—**Locomotive Matters.**—Will Mr. Gobert, "Flying Dutchman," or any other correspondent, kindly explain what the Belpaire system of firebox consists in, and what its advantages are? Also, what is the Bourbonnais type of goods-engine? Is this latter a peculiar type? If so, kindly give a few particulars, &c.—GUIDE YOKE.

[46345.]—**Continuous Brakes.**—Can any correspondent give any information concerning the Creamer, Ward, Loughbridge, and Henderson systems of brakes? What is the medium by which they are worked? I believe they are in use in the United States of America. —GUIDE YOKE.

[46346.]—**M.S. & L.R. Engines.**—Would some correspondent kindly give the dimensions of the new M.S. & L. single engine, and state where it is stationed? —LORD OF THE ISLES.

[46347.]—**Indigo.**—I have a considerable quantity of a solution of indigo, known in the dyehouse as "vat liquor." It has been employed for dyeing woollen; but through having no use for it for some time, it was left in the vat in which it was prepared. On dyeing some woollen last week, I found that the colour given was of a dirty description. On examining the liquor, I found it to contain large quantitites of dyestuff along with dirt. Thinking that if the liquor was freed from the soluble impurities which had got in through the negligence of a man who had the care of the vat, a small portion of the liquor was passed through a filter, and its dyeing power tried again, giving about the same result. What must be done with this; is it to be turned into the river as useless? It contains a large quantity of indigo, which, I think, might be utilised. Any suggestions will oblige—PRO BONO PUBLICO.

[46348.]—**Strophometer.**—Can any of our readers give information as to the construction of Hearson's strophometer or revolution indicator, for which the Society of Arts awarded their gold medal some years ago? —T. AND D.

[46349.]—**Model Steamboat.**—I have a boat about 3ft. 9in long, 9in. beam, and 8in. deep. A slide-valve engine to drive it, ⅜in. bore, 1¼in. stroke. Would "Sunlight" or some brother-reader kindly tell me the best sort and size of boiler that would suit it? A rough sketch would greatly oblige—S'IL VOUS PLAIT.

[46350.]—**Lantern Optics.**—If two slides of equal thickness and similar tone of colouring be placed in the same position in the lantern successively, both slides will be seen equally well without alteration of focus for the second slide; but if a third slide be introduced of similar thickness, but dissimilar colouring, will readjustment of the focus of the objective be necessary, and if so, why?—B. B.

[46351.]—**Leclanche Battery.**—Will Mr. Lancaster or some other gentleman kindly tell me how to prevent oxide forming between the carbon and lead?—J. ELLIS.

[46352.]—**White Fungus on Fish.**—I should be much obliged for a little information respecting the character, cause, and cure of the above? If too voluminous, a reference to a source of information would be very acceptable.—C. O.

[46353.]—**Chemical or Other Action in Aquarium Fittings.** — Would the following materials, composing the supply and waste to, and bottom of tank, in contact with which the water comes during some portion or other of its journey after passing through the ordinary lead service and zinc cistern of the house, be detrimental to the fish—viz., compo gas-pipe, brass, indiarubber tube (white, a portion having turned black during use), zinc, galvanised iron, soft solder, red and white lead, litharge putty, and Portland cement. If so, would the action decrease or cease entirely in course of time, with ample change of water?—C. O.

[46354.] —**Telephone Transmitter.**— In Vol. XXXII., No. 809, p. 56, was given sketch and description of De Locht's pantelephone, and stated that the movable plate may be of metal, cork, or mica. I made a pair with brass plates, but could not get any satisfactory result. It seemed, on listening at telephone (Bell's pattern), that a pair of cymbals were being clashed in the circuit; and on screwing contact-piece more firmly against the carbon disc, I could not get any sound; so after trying several times, I threw them on one side in despair. I now see by a recent article in the "E. M." that they are a great success at the Crystal Palace; also that an induction coil is needed. Would any of "ours," having seen it, kindly give particulars as to thickness of diaphragm, and in what part of transmitter the coil is inserted; also gauge, and amount of primary and secondary wires? I am not able to see for myself, being too far away.—ON GUARD.

[46355.—**Photo. Enlargement.**—To MR. LANCASTER.—Would you inform me how to make an enlargment on sensitised paper, or recommend a cheap book describing it? I want full particulars. I have a quarter-plate lens and camera, and a friend has a magic lantern, if that is required in the work, and oblige—H. C. F.

[46356.]—**Analysis of Alloys.**—Would any of your chemical readers kindly explain the *modus operandi* for determining, separating, and estimating weight of the respective elements contained in an alloy supposed to consist of copper, zinc, tin, antimony, and a trace of iron, giving the reaction in each case?—A LANCASHIRE ARTISAN.

[46357.] —**Clock and Watch Making.**— To "ALFOJOE" AND OTHERS OF THE TRADE.—Encouraged by the example of C. R. Beaumont, I beg to ask if it would be possible for a man 30 years of age to learn the trade? I may say that I have received a fair education, and take great interest in mechanics, &c. I should like to learn the trade if possible. Could I get anyone to teach me if I went for some time for nothing? Would I have any premium to pay? Any advice would be most thankfully received by—NO TRADE.

[46358.]—**Galvanometer.**—Would someone kindly give full particulars of the instrument used by the inspectors in the postal telegraph department of the Royal Engineers? Is it a sine, or a sine and tangent combined? It is carried in a leather pouch, like field-glasses, and is used with the resistance coils. The instrument I refer to is in a brass case, about 5in. dia. Is it graduated with degrees? The one I saw (over five years ago) was very delicate, and served its purpose well. Fullest details will oblige—M.M.I.So.S.

[46359.]—**Gilding Watch-Plates.**—Can any of your readers inform me how the frosted appearance on watch-plates is produced? I have tried to do it, but cannot do it to satisfaction.—H. COHEN.

[46360.]—**Roofing.**—A small villa, much exposed to all winds, is to be covered with felt and slates. What kind and size of slate would be best?—should they be hung on one or two nails? Could anything else be put on felt without damaging appearance? State difference in price per 100 square yards, and oblige—INGLE.

[46361.]—**Bicycle.**—I propose to have the extremities of the fork a little turned back, like the letter J. It would give it elasticity, and a tendency to run in a straight line. The strain upon the arms would be relieved, and the saddle could be moved further back. Has it ever been tried?—INGLE.

[46362.]—**Cast Steel.**—I shall be glad if some of our practical correspondents will tell me how to erect a furnace for casting about 10 cwt. of steel suitable for pit-box wheels and pedestals; also, what kind of metal is used for mixing and making steel?—WIGAN.

[46363.]—**Turning up Cart-Wheel Axles.**—Would someone kindly give a sketch of a simple self-centring tool to hold brass caps for cart-wheel axles in a lathe while they are turned up?—L. W.

[46364.]—**Preservation of Teeth.**—Would Dr. Edmunds kindly inform of a remedy for small black specks on the teeth? I think a few hints on the preservation of the teeth would be thankfully received by many.—G.

[46365.]—**Income-Tax.**—I shall feel grateful for advice. My income from all sources is, say, £210 per annum (£40 pension, £40 parish officer, £80 on business, and £50 improved ground rents). I have always understood that in paying Income-tax on such an amount a claim of £120 is allowed off, which, in my case, would leave £90 to pay on. This I have hitherto done, but this year the order of things is altered; the Assessor of Taxes demands 5d. in the £ on the £40 as parish officer, but I argue that I have already paid on £90 (£40 pension, and on £50 ground rents), and if I pay on the £40 demanded it will be paying on £130, and a claim of only £90 off. The Assessor states that all pensions and appointments must pay on the full amount, no matter how small—even if the whole of the income should be but £50 a year derived from either a pension or appointment, that sum must pay Income-tax. If this is law, surely it is a robbery, and shall be glad to know if I am not entitled to a claim of £120 off under the circumstance stated.—J. W.

[46366.]—**Leather for Bellows.**—I am making a pair of double bellows for blowpipe and other use—will some reader kindly inform me what is the right kind of leather to use? Hints in making will also oblige—NEMO.

[46367.]—**Furnace.**—Will some obliging reader explain to me what should be the difference in construction of a reverberatory furnace for reheating iron, using anthracite coal, and the same kind of furnace using bituminous coal? Also, what is the best method of distinguishing the one kind of coal from the other?—ADRIAN.

[46368.]—**Clock.**—I have a Yankee lever watch I want to take to pieces and cannot. Will any kind reader help me out of the difficulty? The rim at the back seems fast at each side. I have undone all screws visible. Does the winder and hand-setter come off before the back?—ANXIOUS AMATEUR.

[45369.]—**Vacuum Tubes, and What Can be Done with Coils.**—TO MR. W. J. LANCASTER, "A. W. S.," "J. B.," AND "H. B. T. S."—Many thanks to the above gentlemen for their information relating to V. T.'s and Coils. To Mr. W. J. Lancaster and Mr. A. W. Soward, I beg to say that I will be most thankful for any information they will kindly give as to what can be done with a small coil about ⅜in. spark. I have the ENGLISH MECHANIC for the last fifteen years, and, on looking through them, I see very little about working the coil, though a good deal about making it. I acknowledge that the use I make of the coil is principally for amusement; but, still, I do not lose sight of the "hidden mysteries" altogether. I have made several devices or designs with the 6in. tubes on black-boards, with connecting wires carried along at the back, the ends merely coming through the board in the form of hooks on which to hang the tubes, and succeed perfectly in the illumination of five or six tubes thus arranged—that is, with one end of them—and from what the aforesaid gentlemen say, I suppose I must not expect more—that is, that both ends will show with equal brilliancy.—W. R. C.

[46370.]—**Lathe.**—In Volume XXXIV., No. 876, p. 420, I see drawings of an amateur's lathe; I think it is a very handy one. Will Mr. Evans or some kind friend help me in the matter? I want it to be self-acting, and about 3ft. between centres, and 4in. from top of bar to centre. How am I to bore holes in standards true, for bars to go through, as for rest to slide on, as the bars want to be perfectly true? Ought the bars to shoulder at the standard face-plate end of spindle? Must the bars be tapped, or will hole drilled and pins hold them tight? Will it be best to have the screw in centre of bars, or to run by the side through stud? Can it be driven by the screw? I mean a pulley keyed on live spindle, and a square bar run along the lathe-bed turned at ends. A strap off pulley on live spindle on pulley on square bar, strap off another pulley at other end of square bar on to pulley on end of screw, the screw to run in bearings with two collars and nut, or hole in rest tapped for screw to thread in. Must the screw be turned and chased in the lathe, or can it be made to work freely tapped in the ordinary way with stocks and dies? Would it not work better in centre? As regards the spindle, I have taps and dies from ⅜ up to ¾. Will any of these do to tap live spindle to screw face-plate in? How am I to proceed to make the rest? Must there be a nut fitted in the middle of that for screw-thread to work through? If so, how is it done? Can it be fitted in two, so when loosened to slide up the bars faster (the rest I mean) instead of screwing both ways? Are the crossed legs halved together strong enough? Will the lathe vibrate at all? Would angle-iron be better? If screw has to be turned and chased, what will be probable cost? Likewise bars turned true 1in. round—is 1in. round sufficiently strong? The slide-rest looks the most difficult. Any information will be thankfully received by—A CAMBRIDGESHIRE BOY.

THE longest railway in India is the East Indian with 1,504 miles; next comes the great Indian Peninsular with 1,275 miles. The Madras follows with 858 miles; the Sind, Punjaub, and Delhi with 663 miles; the South Indian with 645 miles; the Rajputana with 489 miles; and the Bombay, Baroda, and Central India with 444 miles.

ANSWERS TO CORRESPONDENTS.

◆

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

The following are the initials, &c., of letters to hand up to Wednesday evening, March 8, and unacknowledged elsewhere:—

H. HOLT.—W. Grove.—J. L. Stothert.—Rev. J. Lamont.—J. Terras.—A. Pigott.—D. H. Littlejohn.—F. York.—J. Mather.—C. S. Stock.—Jas. Wilson.—R. W. Armstrong.—J. B. Stephen.—Prof. Patrix.—Rev. J. B. Annesley.—D. Browne.—W. L. O.—Tindal.—Joiner.—Ladle.—Guyot.—Sam Weller.—Summit of England.—X. Y. Z.—N. W.—Conoid.—H.—Les Dents.—Progress.—H. A. Wassell.—North Briton.—Constant Reader.—Subscriber.—Orderic Vital.—Bevel Wheel.—H. L. Dunkin.—Isomeric.—R. E. B.—J. E. Ford.—Chepstow.—Novice.—Dome Joint.—Bramwell.—Enquirer.—Hot Iron.—A. S. T. E.—Pollockshaws.—Diamond.—J. C. King.—H. S. P.—R. W.—Jack of All Trades.—T. G. Elger.—Rough Diamond.—E. Gobert.—E. C. S. E.

A NEW VOLUME.

THIS number is the first of Volume XXXV. Readers willing to oblige us by recommending "ours" to new subscribers should do so now, when a new volume is commencing. The index to Vol. XXXIV. will be published in the number dated March 24, and cases and bound volumes will be on sale shortly after. Readers desirous of making up their sets for binding the last volume are recommended to do so at once, as the back numbers soon run out of print.

D. P., York. (There is no special law affecting apprentices to electricians. If their parents and guardians imagine that their masters are neglecting them—nine parents out of ten blame the master when they should wake up their lazy sons,—they have their legal remedy, which any solicitor will point out. Hours of working vary, but average nine hours a day.)—CHIMNEY POT. (It smokes when the wind is S.W., because some taller building or similar obstruction hinders the draught. No universal remedy can be named; but, speaking generally, we believe Boyle's chimney cowl is the best thing you can use. See advertisement pages of the *Building News* for illustration and description.)—FIDDLESTRING, PAGANINI, AND OTHERS. (We cannot spare any more space for queries as to the value, age, &c., of real or fancied old violins. Nine out of ten are rubbish, and the merits of the tenth can only be appraised by a connoisseur who has *seen* the instrument.)—JOHN LANE. (What you ask would take a volume to give in outline only. There is a book published by Churchill and Co., by Dr. Geo. Wilson, which would give a great deal of the information asked for, but we forget the title. Get the last "Public Health" Act, and read that and the statutes it superseded and consolidated, and then wish, as all sensible men are wishing, that one of these days Parliament may have the time and inclination to pass a really comprehensive and reasonably perfect code of sanitary laws, instead of wasting its time as at present.)—ONE AND ALL. (It is a question for a valuer or surveyor. We cannot deal with matters relating to cost and value of houses in "queries.")—GLENESK. (See a surgeon, It may be dangerous; but no one can possibly say without seeing you.)—A SUFFERER FOR FOUR YEARS. (Such ailments frequently last for years, and then disappear. Temperate but good living, and abstinence from beer and spirits—except when ordered by medical men—are the most likely means of assisting Nature to a cure. It is more than probable that you are suffering from inherited disease.)—GEREBE ADMI. (We believe not; but you had better address the Secretary. The Society and its publications seem alike in a backward condition.)—IN TROUBLE. (You must employ a solicitor, and let him state your case to counsel. On production of counsel's opinion that you have good grounds for proceedings, the Judge of the Divorce Court will allow you to sue *in formâ pauperis*. You had better consult your solicitor on the question of damages.)—H. HOLT. (Many thanks; but we fear we could not spare the space.)—JOHN TYLER. (You had better communicate direct with the correspondent you mention. Long before his reply can appear the ten days will have elapsed.)—A SUFFERER. (Most probably indigestion. See back numbers.)—W. P. (By passing steam through incandescent anthracite or coke. See reply 46155, last week.)—ENGINEER. (See articles on the subject in No. 551, p. 110, and No. 552, p. 135; also pp. 192, 195, 318, 240, Vol. XXV.) C. L. (It is clear that something is the matter with a dog whose coat has been coming out during six years. You would probably find that a change of diet, with abundance of exercise, will effect a cure.)—CITRUS. (If you will look through the last three numbers you will find some remarks about the audiphone and instructions for making it.)—J. D. F. (See recent back numbers. Perhaps it is not damp in the wall, but vapour of the air condensed on the interior surface. If the wall is damp from driving rain, paint it with tar thinned with turps, or coat with Portland cement. 2. See p. 176. The best angle for general purposes is 37°; but for special purposes it may be modified to suit other conditions. For vines only the angle would be much greater in order to secure greater length of rafter, say, 60°. The guiding rule for general purposes is that the angle should be equal to the latitude of the place, modified, however, at lat. 1° and 70°, for instance. 3. Certainly not. One much more serious than the other. As to their curability, much depends on the constitution of the patient. That being good, the answer is, Yes.)—WYKEHAMIST. (The terrestrial has more lenses, in order to present the objects in their natural positions. Dents of no moment.)—P. A. T. (Butter analysis is not an easy task. See p. 14, No. 495, and the indices to Vols. XX., XXI., XXIII., and XXIV. 2. Get Mr. Fletcher's list, and look through the indices of last five vols.)—NOVICE. (You do not say whether brick or plaster wall; but the answer is the same—good paint. Use the cheapest colours until you obtain a good surface for the finishing coat.)—MAGGIE LAUDER. (A simple test for butterine is said to be examination of a knife which has been passed through the same, the blade being held up to the light so that the appearance of the little strings at the edge can be seen. The difference in appearance between butter and butterine is said to be remarkable; but the comparison must be made to be understood.)—DECIMAL. (The rules are given in Molesworth's Pocketbook and similar works—probably in one of Calvert's Mechanics' Almanacks; but if you want something more than a mere rule for calculating the strength, get Wilson's "Treatise on Steam Boilers," Lockwood and Co.)—MILLWRIGHT. (Your best plan is to apply to the Agent-General for the Colony, Sir F. D. Bell, 7, Westminster-chambers, S.W., and it is advisable for a man with a wife and family to secure a situation before emigrating, unless he has sufficient money to keep his family while looking about for work.)—W. FANN. (See that your "iron" is well tinned and sufficiently hot; the solder will then follow wherever you lead it.)—W. J. WARNE. (In the same, preferably.)—SUFFERER. (There is some constitutional disorder which personal examination by a medical man may discover; but, meantime, you may obtain much relief, and can do no harm, by bathing the feet in water as hot as it can be borne.)—R. J. W. (Special signals, probably for goods trains; but impossible to say without knowing the "rules of the road.")—WOULD-BE AMATEUR TURNER. ("The Lathe and its Uses," Trübner, Ludgate-hill, E.C., 16s.)—C. HORACE PHILLIPS. (By means of a dynamo-machine. See a series of articles on the principles involved on pp. 567, 591, 615, Vol. XXXIII., and pp. 8, 33, 58, 85, and 106, Vol. XXXIV. There are also many practical directions in recent back numbers.)—MERCURY TUBE. (Can you not put some more in, if part has been lost? As put, the query is a puzzle.)—A. W. G. (Move the regulator to the side marked "fast," or get a watchmaker to do it.)—E. C. S. E., L'pool. (If you look through back numbers you will find an answer to your queries. You will want a battery of about 30 quart Bunsens to do any good with an incandescent lamp. 2. Directions for constructing aquaria have been given many times. See p. 537, No. 541, and p. 153, No. 552; also the indices of back volumes.)—MOSSVALE. (Any good glue; but perhaps Russian is best for the purpose. 2. No; see many of the papers on the subject in recent numbers. 3. Dip twice in boiling logwood solution, drying between each dip; then go over with solution of sulphate of iron. All the questions answered many times.)—PHŒNIX. (Where "grammes" is the term, it is always understood as a weight.)—ONE WHO WISHES TO ENTER. (By apprenticeship. You might obtain particulars of the Government service by applying to E. Greaves, Esq., Engineer to the Postal Telegraph Department, St. Martin's-le-Grand, E.C.)—VERITAS. (Full particulars can be obtained on application to the Registrar of the Pharmaceutical Society, 17, Bloomsbury-square, W.C.)—G. H. MATTHEWS. (Better try a speculum, for it is clear you have little idea of the nature of the work. You will, however, find full particulars in back volumes. See recent indices, including that to be published on March 24.)—RODRIGO. (If you have the hundred cells made you must procure a "regulator," or so arrange two pieces of carbon-rod that the current will pass from one to the other. Good examples are illustrated on p. 230, No. 764, and p. 573, No. 778; but a simple form may be made with two pieces of carbon and the regulation effected by hand.)—ZEALAND and H. LEES. (Advice to emigrants is always given with extreme caution, unless they are personally known, and their characters understood. "Zealand" has friends in New Zealand who could surely advise him better than strangers; and H. Lees has left the matter so long that he wants direct answers. We advise them to read some of the handbooks and to consult some of the agents of the colonies to which they propose to emigrate.)—AMATEUR ELECTRICIAN, Cork. (We answered you on p. 603, No. 883. Instructions for making coils have been given over and over again, and we cannot spare the space to repeat mere elementary information. See reply 46186, No. 884.)—BAND SAW. (You will find two methods of brazing band-saws illustrated in No. 628. See also Nos. 523, 524, and the indices of back volumes.)—CAMERA. (Look up what has been written in recent numbers. and the last three or four volumes.)—JOHN KERSHAW. (Probably the recipe given on p. 520, No. 749, is what you require.)—JEWELLER. (Answered fully within the last five months. See pp. 145, 168, 189, 193, 216, 260, &c., last volume.)—J. SHAW. (Your query would open the door to a gratuitous advertisement. A private inquiry in the district where such machines are used—say, Leicester—would, no doubt, elicit trustworthy information.)—AN OLD READER. (See p. 575, No. 830, and p. 376, No. 848. If for an existing pad, dissolve aniline with acetic acid and water into a paste, and add a little glycerine.)—JUMBO. (The cordial is made by dissolving oil of peppermint in rectified spirit which makes the essence: that is diluted with white, tasteless, proof spirit, and is reduced with water, sugar being added to sweeten and alum to "fine." The oil is obtained by distilling the fresh shoots of the flowering plant, and in commerce contains, as a rule, about one-third of rectified spirit. 2. You will find plenty of devices in back volumes. All that is needed is to provide the hand with a sufficiently long contact, or cause it to let off a trigger which will make contact and keep it until broken.)—FRANK. (Perhaps your manganese is in too fine a powder, and perhaps you had not given sufficient time for the solution to soak through. At any rate, "try again." 2. Look through recent numbers, and watch those to come for medical coil.)—F. R. (Books descriptive of the machines, but none giving dimensions and details. You have seen, we presume, what has appeared in recent volumes.)—E. E. R. Tratman. (Our space would not admit of it, for the subject is of limited interest. You can obtain photos of Mr. Bleasdale, 136, Park-road, Aston, Birmingham. 2. We do not think you will find anything better than pins, using large and thick ones, cut short near the head.)—W. M. (It is worked to a putty-like mass in a masticator, and forced into iron moulds.)—Rustic. (See p. 212, No. 867. A simple "cure" is to coat with hot limewash, and brush off when dry; but the only thorough remedy is to have the pot regalvanised.)—G. A. H. (See preceding answer.) —Sefton. (You can do nothing. If, when all the assets are realised, there is a balance, it will be divided among the shareholders; if there is a deficit, you will have to make it good amongst you to the amount of your shares, or, if the liability is not limited, to the full amount. The matter is very young yet, and liquidators are not in a hurry as a rule. We have, within the last few days, received the last instalment paid in the liquidation of a company which has taken seventeen years to arrange.)—An Amateur Painter. (Yes, of course it *is* the drying ingredient. What you mean by "doing harm amongst varnishes" we cannot imagine.) —P. W. (The query was fully replied to, and we do not think the querist wanted any new theory expounded to him. We have no space to discuss your measurement theory – hundreds of things of more practical importance are standing over in the present crowded state of our columns.)—Shoe Black. (Dozens of recipes for blacking have been given in back vols. One, a very good one, is given in letter 16233, p. 69, No. 757.)—Eclectic. (1. No. 2. We cannot, in this column, decide who are the "best" makers of any articles. 3. The construction of the glycerine barometer was described on p. 532, No. 829. 4. We do not know what you mean by the "effects of magnetism." 5. Longmans' "Textbooks of Science." See advertisement on p. vi. in No. 882.)—Electron. (See answer to "One who Wishes to Enter.")—Tubal Kain, Alfojoe, An Old Photographer, Jack of All Trades. (In type.)

THE LATE "SECONDS' PRACTICAL WATCH-MAKER."

We have received the following additional contributions since our last issue, and hope our readers will help us to close the list as quickly as possible. Mrs. Coates has also received five shillings direct from Mr. George Bourn, of London, which she wishes us to acknowledge.

Tricycles and Bicycles for the Season.—The Excelsior bicycles and tricycles manufactured by Messrs. Bayliss, Thomas, and Co., of Coventry, are too well known to need any praise; but for the present season the firm is introducing some new designs which may appropriately receive a word or two. One of these—the Victa Excelsior Tricycle—is a double-driver, the lightest and most compact machine of its kind—the Victa D.E.H.F. bicycle is its counterpart; another is the folding Excelsior tricycle made on Fletcher's patent, which, by taking out a taper pin, unhooking brake-chain, and unslotting guide-rod, can be folded up so as to occupy little, if any, more space than a bicycle. Perhaps the most taking novelty is the Duplex Excelsior Tricycle, which is so built that both riders drive, sitting one behind the other, while by removing the additional seat and cranks, the machine is reduced to the appearance of an ordinary tricycle, and weighs only a few pounds more. Messrs. W. Gorse and Son, of Birmingham, are introducing "The American," a bicycle which, for lightness and rapidity, compared with price and quality of material, is claimed to be the cheapest first-class machine in the market.

Throat Irritation.—Soreness and dryness, tickling and irritation, inducing cough and affecting the voice. For these symptoms use Epps's Glycerine Jujubes. Glycerine, in these agreeable confections, being in proximity to the glands at the moment they are excited by the act of sucking, becomes actively healing. Sold only in boxes, 7½d. and 1s. 1½d., labelled "James Epps and Co., Homœopathic Chemists, London." A letter received:—"Gentlemen,—It may, perhaps, interest you to know that, after an extended trial, I have found your Glycerine Jujubes of considerable benefit (with or without medical treatment) in almost all forms of throat disease. They soften and clear the voice.—Yours faithfully, Gordon Holmes, L.R.C.P.E., Senior Physician to the Municipal Throat and Ear Infirmary."

Holloway's Ointment and Pills are never at fault in successfully disposing of skin diseases, scrofulous sores, and scorbutic affections. In all hereditary diseases these excellent remedies may be relied upon, and by their means the most delicate may become strong, and the foulest blood may be gradually changed into the purest fluid.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m. on Wednesday to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

◆◆◆

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

◆◆◆

All sorts of **Instruments** and Apparatus exchanged for others. Good value allowed.—Dr. Caplatzi, Science Depot, Chenies-street, Tottenham Court-road. Established 1862.

For Sale, 4ft. planed iron and steel, mechanic's **Lathe,** 3in. centre. Offers in Bicycles or Tricycles.—G. J. Bragg, 10, Queen-street, Colchester.

Exchange **Stereo Camera** and Lens for pair of 5in. Lantern Condensers, or offers.—O. Lange, 23, Newstead-road, Liverpool.

Strong **Horizontal Engine,** 2in. bore, 4in. stroke, brass cylinder, and feed pump, nearly new, in perfect order, in exchange for microscope to value £3.—R. Webb, 2, Hope-street, Hackney-road.

Three-vol. **Novels,** in good condition, for exchange. What offers? Shocking coil or high music-stool wanted.—Mr. Salter, Cromer, Norfolk.

Lathe Parts.—4ft. planed Iron Lathe Bed, pair of standards, and 3-speed driving-wheel; exchange silver watch, drill chuck, &c.—Mitchell, Park-street, Keighley.

Wanted, **"The Universal Measurer and Mechanic,"** by Abraham Fletcher, 1781, for scientific Books, or value.—W. H. G., 19, Albert-road, Braintree, Essex.

"Cassell's Popular Educator," six volumes bound in three, perfectly new and unsoiled, cost £2 5s. Will exchange for long-distance Telescope or offers.—F. J. Cunningham, Young Men's Society, Cork.

"Cassell's Popular Educator," bound in three vols., almost new. Will exchange for ½ Objective for Microscope, or offers.—C., 15, Marmion-road, Liverpool.

Choice rapid Carte-de-visite **Lens.** Exchange for small Doublet Lens, or good Single Lens or offers.—E. B. Fennessy, Pallas Green, Limerick.

Excellent **Camera and Lens** (Chevalier), really useful apparatus, cost 50s. Exchange good Apparatus for copying circulars, &c., in black; or sell.—Platt, Normacott, Longton.

Books.—"Keble's Occasional Papers and Reviews," "Woodcroft's Origin and Progress Steam Navigation," "Clegg's Architecture Machinery," "Arago's Life Watt." What offers? —W. Ambrose Taylor, Penzance.

Concertina (the Paragon). Powerful tone 30-keyed baritone, Anglo, steel vibrators, new, in lock case; splendid instrument, cost £5. Offers?—James Southey, Wellington, Somerset.

I have two **Bicycles,** 48in. and 50in. Will exchange anything useful.—apply to E. Childs, Sherborne, Dorset.

"English Mechanic," from May 3rd, 1878, to present time. Two numbers missing. Exchange Mathematical Instruments, or books on Building Construction.—W. T. Johnson, 147, Portland-road, Notting Hill.

"English Mechanic." Will exchange the last 24 vols. up to date, X. to XXXIV. inclusive, unbound, clean, and complete, with indices. For Photographic Apparatus or Bicycle. Offers.—W. James, 6, Percy Circus, Islington, W.C.

Parcel of **Artificial Sapphires** (five dozen) in exchange for small Galvanised Iron Garden Barrow. (Sample Stone sent for six stamps).—K., 1, Rose Villas, Sudbury, Middlesex.

Wanted, Dallmeyer's **Stereographic Patent** Lens. Will give in exchange a Stop of Principal Metal Pipes, new, voiced and tuned.—S. Arlidge, Organ Builder, Kingsley Park, Northampton.

Wanted, a good **Cloth Background,** medium tint. Will give in exchange a 10 by 12 German Glass Bath; in mahogany case, complete.—J. Arlidge, Photographer, Kingsley Park, Northampton.

Strong back-geared foot **Lathe,** 9in. centre, wood bed, 7ft. 6in. long; cost £20. For Iron Saw Bench.—Jas. Baigh, Burton-in-Lonsdale.

"History of England," quite new, splendidly bound, gilt rims and clasps; cost 45s. Exchange for good Dulcimer.—M. C., Duleek, Meath, Ireland.

Excellent new **Horizontal Engine,** 3¼in. cylinder, 5½in. stroke, with flywheel and pulley, turned and polished; any reasonable offer.—J. Coatman, 381, Bolton-road, Darwen.

Lathe Heads, pair 8in. centres, back-geared, 5 steel centres, face-plate, rest, and socket, all in perfect condition; any reasonable offer.—381, Bolton-road, Darwen.

Sweet-toned **Organ Accordion** on stand, and foot-blower, cost £6, in perfect order. Wanted.—Bicycle, Harmonium, English Concertina, or Shuttle Treadle Sewing-Machine.—Wm. Shackleton, Market Hall, Accrington.

2½ H.-P. Horizontal Boiler, guaranteed sound. Exchange for chest of tools, or anything really useful.—H. Bibby, St. John's-road, Longsight, Manchester.

Wanted, first-class **Landscape Lens,** ¼ or ½-plate. Will give Photo, or other apparatus.—J. Rutherford, Jardington, Dumfries.

Good **Dagger,** best steel, with pearl and German silver handle, in sheath, exchange for small revolver.—J. Gidley, 44, Dean-street, Soho.

Bicycle, 52in. (bright), roller bearings, and cash exchanged for screw-cutting lathe, 4 or 4½in. centre, gap-bed preferred.—38, Victoria-street, Sheffield.

Splendid white cane **Roach Rod,** double winched and line, folding ring and net.—E. Baker, 6, Prince's-terrace, Maldon-road, Kentish Town, N.W.; for Bicycle Lamp and Alarm.

Table Engine and Vertical Copper Boiler, ½ H.-P., in working order, for 5in. screw-cutting lathe.—Address as above after 6 p.m.

Lathe, 4in. back-geared, compound slide-rest and Tee, for 54in. bicycle.—Address as above, after 6 p.m.

Model Locomotive Copper **Boiler,** 6in. cylinders and steam tap complete, for model electrical engine.—Malvern, 25, Shirlock-road, Haverstock-park, N.W.

£5 Day and Night **Telescope,** £2 Wire Dulcimer, hand-sewing machine, all perfect, for Harmonium out of order, or what offers?—31, Central-buildings, Kendal.

Small **Blast Forge,** suitable Locksmith, Gasfitter, also boiler, 5in. by 16in., and tricycle, works hands and feet; offers.—A. W., 16, West-street, Maryland-point, Stratford, Essex.

Two good toned **Violins** and Bow, for Bicycle, or offers.—G. Hughes, 55, St. Arnaud-street, Edge-hill, Liverpool.

For Sale.

"The Night-light Clock." Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—F. Robertson, 13, Greek-street, Soho, W.

Band Primo.—A Tutor for all Band Instruments. "A Book which every Bandsman should have." Price 5s., P.O.O. T. Rawson, 114, Heaton-lane, Stockport.

Harmonium, £5; 7 stops, walnut case, full compass, ivory keyboard; bargain.—55, Collier-street, King's-cross.

Lantern Photographs, 10,000, with readings, from 6d. plain, 1s. coloured.—A. Pumphrey, Emily-street, Birmingham.

Lantern Photographs for Hire. List and sample picture for 8d. in stamps.—A. Pumphrey, Emily-street, Birmingham.

Triplex Lantern, **Achromatic Lenses,** full size, best light, limelight excepted, 42s.—Pumphrey, Emily-street Birmingham.

Complete **Limelight Apparatus,** equal to 200 candles, 90s. List of Apparatus 3d.—A. Pumphrey, Birmingham.

Chromatrope, with 5 designs and Eidotrope, complete from the manufacturer, 10s.—A. Pumphrey, Emily-street, Birmingham.

Harmoniums, second-hand; returned from hire. All prices.—Venables and Co., 187 and 189, Essex-road, Islington.

Pianos, second-hand; returned from hire. Extensive showrooms.—Venables and Co., 187 and 189, Essex-road, Islington.

Working Drawings by Practical Draughtsman at moderate charges. send particulars or rough sketches of requirements to H. Burch, 111, West High-street, Salford, Manchester.

Magnesium Ribbon, burns like the electric light, 3d. per foot, post free.—L. Rowland, South John-street, Liverpool.

Prof. Kennedy, Dublin, will send his Infallible Corn or Bunion Cure (state which) for 14 stamps

"The Feet, and How to Treat Them," by Professor Kennedy, Dublin. Pamphlet sent for 2 stamps.

Notice.—If Prof. Kennedy's Corn or Bunion Lotion fails to cure, the money will be returned.

Mitre Machine for picture-frame makers (registered). Send for Illustrated Circular, post free.—Booth Brothers, Dublin.

FRIDAY, MARCH 17, 1882.

RAILWAY SIGNALLING APPLIANCES AT THE CRYSTAL PALACE ELECTRIC EXHIBITION.

RECENT railway accidents which have exposed the defects of some of the existing methods of signalling have naturally made the appliances exhibited at the Palace Exhibition objects of much attention, and as nearly every really useful system is shown in working order (that is, when not disarranged by the carelessness of experimenters), the public have an opportunity, not often afforded, of becoming acquainted with the signalling arrangements commonly adopted on railways. Besides the standard systems, as they may be called, there are, however, several novelties which are more or less adapted to remedy defects which are inherent in or appertain to the well-known devices, and these we shall endeavour to describe as minutely as possible. The London, Brighton, and South Coast Railway Company exhibit the methods adopted on their line at various periods, including Saxby and Farmer's union of "lock" and "block," while the London and South-Western show Preece's system in working order for a block section, with three signal-repeaters to indicate to the signalman in the boxes the position of the semaphore arms. Mr. Spagnoletti's arrangements as employed on the Great Western are also shown, and as we have previously mentioned, Mr. C. V. Walker, the electrical engineer of the South Eastern, exhibits a unique and chronologically arranged collection of instruments used for signalling purposes. All of these are tolerably familiar to those interested in the subject, as they are fully described in the text-books; but in the exhibit of W. R. Sykes, shown in very large scale model, we have perhaps the most advanced and most perfect combination of the electric lock and block. This system has been in use for some years on the London, Chatham, and Dover, and the Metropolitan District, and is probably as near perfection as it is possible to go. It is shown as working between three signalling points, and those who are sceptical can try for themselves how far it is possible to break it down, and set signals so as to cause an "accident." The system is based on the mechanical union between the lock and block, and every signal given requires the attention of at least two signalmen. Thus, suppose we designate two signal-boxes as A and B, A cannot lower his semaphore until B releases his lever, and per contra, B cannot lower his semaphore for a train in the opposite direction until A has released the lever by electrically removing a pin from the stop in the lever. Suppose a train to be approaching A's box, and travelling towards B's, A sends the call to B, and receiving "line clear," sends another signal which releases the lever in B's box, and enables the latter to pull off his signal, which he can put on again, but not "off" until he gives "line clear" a second time. Thus two trains cannot be in one block-section at the same time, except by consent of two signalmen. Similarly, by combinations of electrical and mechanical arrangements, it is impossible to pass trains by signal while a siding is open for shunting, as the fact that the points are open for the siding effectually locks the main-line signals. On the other hand, points for sidings cannot be opened if a "line clear" signal has been given to a main-line train, until that train has passed out of the section. Thus, unless two signalmen at different boxes make the same blunder, it is impossible for an accident to occur, provided the drivers of the trains pay attention to the signals. It will be readily understood that such a system would have prevented the Canonbury "accident," which may be taken as an extreme case of railway blundering that would have been simply impossible if the signalling arrangements had been on the plan just described. All the systems we have mentioned are, however, thrown out of use by dense fogs, and by occasional defects, and attempts have been made by enthusiastic inventors to persuade the railway companies to employ what may be termed automatic systems, not that they are really automatic, dispensing with the services of signalmen, but as complementary signals appealing more directly to the driver than the semaphores, for which it may be said he has to look out. Even in the case of fog, however, the Sykes' system has been found to answer remarkably well, for the simple reason that a signalman cannot allow a train to leave until the signalman in advance has released the lever. Still, fogs are not unknown in London so dense that the driver cannot see even the post, let alone the semaphore, and in such cases fog-men are employed—introducing yet another element of human fallibility. To provide for such conditions as these several devices in the shape of electric gongs working in connection with the signals have been invented, and one of the simplest of these is Sullivan's electric fog and night signal, shown in a working model in the Eastern Gallery at the Palace. This arrangement is simple, not likely to get out of order, and certainly more trustworthy than the average fogman. It consists simply of a small bar placed parallel with the rail, and projecting slightly above its surface when the signal-arm is "on," or at danger. The wheel of a passing engine depresses this bar, and rings a powerful gong in a box near the post; while, should the signal be "off," the bar is drawn below the level of the rail, and the gong is not sounded. The signal is entirely under the control of the signalman, and can be worked either electrically or mechanically in connection with or separate from the semaphore. It is, in fact, a type of a useful class of signals, which can be so arranged as to supplement the ordinary semaphores in clear weather, and to act as substitutes in the event of fog or derangement of the apparatus.

The British and Irish Telephone Co. exhibit a working model of Redcliffe's fog-signal, which differs so far from that just mentioned, that the "signal" itself is given on the engine. In this arrangement we have the usual magnet and armature, the latter carrying a projection, which rubs against a long lever carried alongside the engine, in about a line with the centres of the driving-wheels. This lever actuates a small semaphore placed on a level with the driver's eyes, and also sounds the whistle,—a crude idea, which does not commend itself by the finish of the model. Several better devices have been described in our back volumes, and so long ago as Feb. 5, 1875, we gave an account of Sir D. Salomons' system, which was so far complete in details as not only to call the driver's attention, but actually to shut off steam and apply the brake for him. That system (see p. 516, Vol. XX.) necessitated a central insulated rail, which was so connected to the engine that on the latter entering a block section already occupied a bell would be rung, or, as before explained, the steam might be automatically shut off. A practically identical system was patented last year by a Mr. Putnam, of New York, and in the Concert-room Gallery, Messrs. Apps exhibit a nicely-finished working model of the system invented by Mr. T. T. Powell, of Harrogate. In this we have the insulated centre rail or wire in contact with the train by means of light wheels and rods, a couple of signal-boxes, and bells, &c. Levers at the side of the rails are depressed by the passage of the train and give notice in the signal-boxes, while tapper-keys on the engine and guard's-van enable either driver or guard to communicate with the signalmen, and the latter can, of course, communicate with them. The model is sufficient to show that a railway worked on this system would form an electric circuit, or combination of circuits, by which not only would signalmen be able to communicate with trains approaching their boxes, but the manager could, by means of an indicator, locate the position of any train at any given time; further, platelayers could inform signalmen promptly of any defect in the road, and passengers could communicate with the driver or guard. The difficulty is the centre insulated rail, which would cost something, and the insulation, we are afraid, would be a source of trouble. In some respects, Mr. Powell's system is more complete than that of Sir D. Salomon's, for the latter breaks his centre-insulated rail into "block sections"; but we do not think that either plan is likely to be adopted for some time. A really useful invention is shown in the Eastern Gallery in the shape of King's patent electric railway signal, which is specially adapted for use on single lines in sparsely-populated countries, or where the amount of traffic will not allow of a competent and ample staff of signalmen. In the model we have a single line with a branch to a siding and three posts, one of which contains a clock capable of indicating time up to 15 minutes, and a semaphore put "on" by mechanical means as the train passes over a lever treadle level with the rails. This semaphore is put to "off" by means of electricity when the train reaches the next post, where, at the same time, it puts the second signal at danger. The use of the clock is not quite apparent, for the inventor can scarcely expect his system to be adopted in crowded districts, but for certain purposes it will be employed in the following way:—The clock, say, is at post A: a driver approaching and finding the signal "off" will see by the clock how many minutes have elapsed since the previous train passed into that block section, and as his engine passes the post it will, as explained above, put the semaphore at danger and the clock-hand back to zero. When the engine passes post B, it again runs over a treadle, which puts the semaphore at B to danger and clears the block section in the rear by lowering the semaphore at A, where the clock-hand again indicates the number of minutes since the engine passed. Suppose post B guards the entrance to a siding, the engine which passes A and enters the block between A and B puts a special semaphore at danger at B by means of electricity, and thus gives warning that a train is approaching, and that the pointsman must be ready to clear or to pass into the siding, as the case may be,—a lever at B working a signal at C to indicate whether the branch or siding is clear. The arrangements are all under cover, and the treadles and other accessories are so arranged that the signals work at the same speed whether a fast or slow train passes; in fact, the details have been carefully worked out, and the system will no doubt find employment in America, Australia, and other places, as well as in large goods stations with long lengths of sidings. Another device worth notice is found in the Southern Gallery, where Dr.

Garau shows a model of his method of communicating with the guard by making the electric connection through the buffers. On pulling the signal cord in any compartment, an arm is thrown out from the side of the carriage, and a bell rung in the guard's van. It is obvious, however, that this method is not to be compared with others, as it depends for its efficiency on the fact of the buffers being in contact, and that is not always the case except, perhaps, on some of the metropolitan lines. Altogether it may be said that although some useful novelties are shown at the Exhibition, so far as railway signalling is concerned, the established methods are the best.

WATCH-CLEANING AND REPAIRING.

By "A Fellow-Workman."

The Verge Watch.

BEFORE I begin I should like to say that it is not my intention to write this for the benefit of general jobbers or improvers. My intentions are to put before the amateur, and those who wish to learn the trade and have not the needy to buy it, the easiest and cheapest way that I know of; so that if I can give any poor novice a start, or any amateurs a few evenings' amusement, without touching their pockets, I shall be satisfied.

First remove the movement from the case. Poise the movement in your left hand so that your thumb comes on the contrate-wheel F. Now the watch should stop. Remove cockplate (D) screw; then, with your tweezers (9d.) take off cockplate, now put your tweezers in front of the pin that secures the hairspring and lever it out, and turn back the balance B until the hairspring is free. After you have removed the balance you can let watch run down; now remove the hands, next the dial (or face); you will be able to remove pins best with the small blade of a knife. Now take off hour-wheel, next, motion wheel, then with your pliers (2s.), remove canon-pinion which carries the minute-hand; then remove regulator (put the screws in a piece of paper, and put R on it), next barrel bridge, if it has one; now the pins in pillars, and take off plate; the barrel-lid or cover is removed by striking the arbor on the opposite side.

Now take upper or top plate, Fig. 2, poise it in left hand with follower stud (B) towards you, and with your long-nosed pliers (1s. 1d.), remove follower, then escape wheel (A), then potence J. Before removing the escape it is necessary to see that the holes are all right, and that it is in order; but I will give that further on. We will presume now that the watch only wants cleaning.

Begin with the pillar or bottom plate (Fig. 2). Brush round and round against the sun (if you brush straight across, it will show scratchy), dapping out the chamfers and hollow places, using the best white chalk (which you should keep in a little box under your bench) until you have removed all traces of dirt and oil, especially round the holes and in the chamfer; if the chalk or dry brush (8d.) does not do it satisfactory you must use another brush, which has been damped with oil and rubbed on a piece of wood, which we will call the *wet brush;* but always finish with the dry brush, and be sparing with your chalk. You must hold the article in a piece of thin unglazed paper while cleaning. Clean the holes with pegwood (2d. per bundle) or dogwood, and sharp at one end, bringing it off to a fine point, cutting off the other end with three sides for cleaning the chamfers. We will call this a *skewer*. Now with your skewer clean out the holes F, E, G, I, first one side and then the other until, by holding it up to the light, the hole looks bright and clean, and the skewer comes out clean. Put this in a saucer under a glass, and take the top plate (Fig. 2): clean this in the same way; be careful of the stop spring (K), also clean hole in follower stud (B, or counter potence). Put this under the glass and take potence (J). Clean escape-hole front and back. In cleaning the bottom hole, be careful not to press too hard. Cut the skewer flat at the point the size of the hole, and keep cleaning until you can see the bottom of the hole. If you should break the point in the hole you must be careful to remove it. It is done by carefully working in the point of a bottoming tool, which should be *smaller* than the hole; as soon as it has reached the bottom it will not throw out any more wood; then go on cleaning again. Next take the cockplate (D, Fig. 3), *dap* out the fretwork. Next regulator H, now barrel, clean out holes, and harbor (C), oil pivots of arbor and put on lid. The cut in the lid should come directly over the hole made for chain-hook; clean follower by holding it in your pliers; clean fusee (K). In cleaning cogs or *teeth*, you must use wet brush first: the teeth should be bright both sides, next centre-wheel, dap out pinion-leaves (*i.e.*, the steel teeth); third wheel, E; contrate, F; escape, A. Now the balance or verge (B). This should be cleaned with the pith of elder, which should be collected in the winter or spring. Select white dead pieces, lay it in a dry place; when you want to use it remove the bark and the pith will be firm, soft, and beautifully clean. Take the balance in your left hand, and press the pith on the verge until it touches the collet (L). Push it on and off until the pallets are clean; if you cannot remove all dirt with your pith, use the point of your skewer, be careful if you use your brush—always lay the balance down with the verge resting on the saucer or pad, and then it will not get broken. Now clean the wheels under the face; hands are cleaned by laying them, face downwards, on a piece of wash-leather, and rubbing them to and fro with your finger; now we will put it together; before you drive a screw, you turn it backwards until you feel it drop; then screw up—never force it.

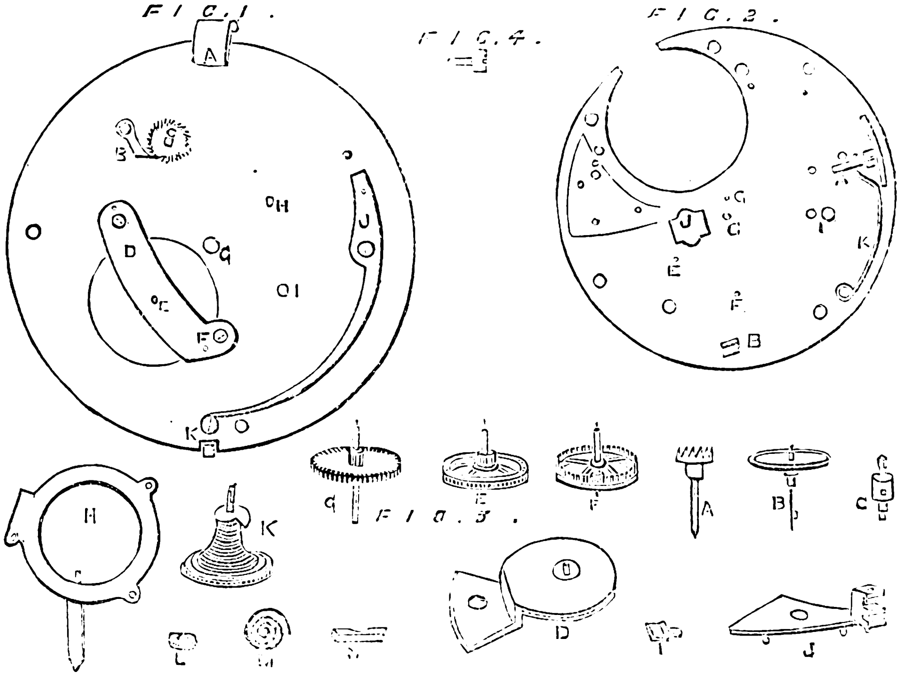

FIG. 1. FIG. 4. FIG. 2. FIG. 3.

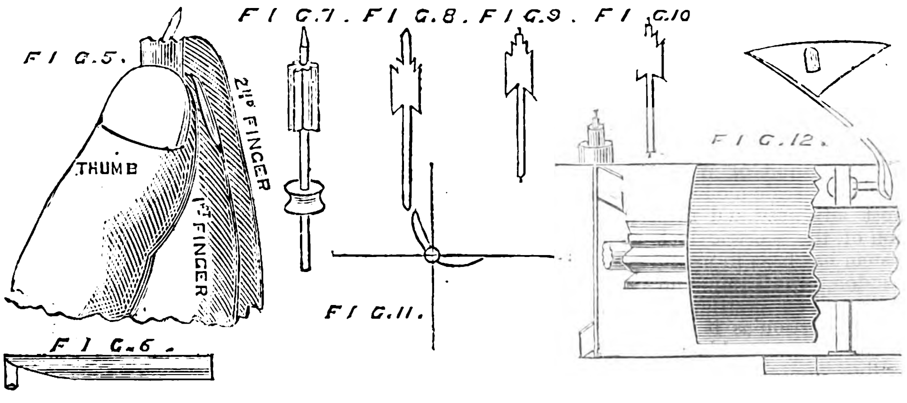

FIG. 7. FIG. 8. FIG. 9. FIG. 10. FIG. 5. FIG. 12. FIG. 11. FIG. 6.

First put on the potence, then put the escape-wheel in its place; if there should be more than one hole, it is generally the hole nearest the screw, but you will see which way the dovetail (N) has been moved; hold the escape-wheel with the forefinger of your left hand until you have fitted the follower; allow a little shake; now take pillar-plate, put in third wheel first, centre next, fusee next, contrate next (barrel next, if there is not a bridge); put on upper plate, place the thumb and third finger under the pillar-plate, and the first and second finger on the upper plate, and with your tweezers put the pivots in their respective holes, while you gently press with your fingers; a short pin comes under the cock-plate, and barrel-bridge and regulator.

(I forgot to say that, before you put in escape-wheel you must oil the holes in potence and follower; a small drill is best; for oiling one dip is sufficient).

Now oil the holes you have cleaned; put in barrel; make sure, when you drive in any screw over the potence, that it does not prise the potence away from the plate; put on chain, set up half-round, put on regulator, &c.; to put the watch in beat, you must try it by means of your thumb on the contrate wheel, whichever way it goes furthest ease it—in this way you will get it true; allow a little end shake. Now put on canon-pinion; if it fits loose, put a small hair out of your brush in to make hole smaller; put on dial (clean it first) then the hands, and your movements are ready for the case, which should be cleaned with wet whiting and a stick, then left to dry, and brushed off with a brush kept on purpose—not your dry brush.

SCREWS.—The cockplate screw is the first which comes under our notice. In fitting this screw, above all others, great care should be taken. Take a piece of steel wire, the size of countersink in cockplate, centre it and turn for thread; it is not necessary to make the thread up close to the head. Take your saw and cut nearly off, return it to the screw-plate, break off; now file the head level, take your saw and make a slot for driver, file off all burrs, put it on a piece of charcoal, and blow to a glowing red-heat, and drop it into cold water, polish the head, and put it on the blue-pan. Fig. 4 is a sketch of a screw as it *should* be made; take care that when it is screwed on that the end does not go beyond the plate; it should go nearly through. You should always take particular care, when fitting a screw to either plate, that the end does not go beyond the inner surface. You can buy screws in the rough, but making them is a good practice for the graver; a screw-plate and taps will cost about 3s.

Escapement.—Now, the escapement is the principal thing. It is composed of the escape-wheel, potence, follower, balance, and cock-plate, which should always be examined before you clean a watch.

Escape-Wheel.—The front of the teeth should never be touched, as that is your only guide; if the teeth have lost their points, you must file at the back with a "balance-wheel file (4d.); hold it in your hand as shown, Fig. 5, you place it between your forefinger and thumb, and place your second finger behind your fore, to act as a support and guide; if you send it to London you can get it properly cut for 6d.; but before you cut it you must find out if the teeth are all of the same length. You cannot do this in the turns; you must place it on the face of a piece of *true flat* Turkey or oil-stone, and work it round and round until all the teeth touch the stone. You can remove the burr from the inside with a piece of slate-pencil, shaped as shown, Fig. 6.

To Put in a Pinion.—Get one in the rough (4d.); send the old one as pattern, which must be removed as follows:— Place the wheel on a stake and drive out with a punch; Figs. 7 to 10 show the progress of the pinion.

Verge.—The pallets of the verge should not stand at right angles, nor should it be too proud (Fig. 11 is about the proper angle). measure from the bottom of the potence to the top of escape-wheel, as shown by the horizontal lines, Fig. 12. Now fit it in your carriage. There are several sorts of carriage, but they are all more or less dangerous; the best I know of for beginners are Figs. 13 and 14. Fig. 13 is a rose made of bone, A and B are two plugs made of peg-wood. Sharp up a piece of peg-wood and press through the rose, cut the bottom end off close to the rose from A to the shoulder of bottom pivot (B); cut off and split in two halves; cut a little crease up the centre of inside, and cut one a little shorter than the other (see Fig. 14). Turn for collet, then balance next bottom pivot, then top pivot. Now place verge on "verge riveting stake" (4d), and, with a spring punch, rivet on balance. If banking-pins are in the potence, you can rivet on balance, but if it (the banking) is on the outside of the balance you must adjust the verge, as per Fig. 15. A is bottom pallet, B is top pallet; when the pin on the rim of balance is exact between the two bankings, the pallets should stand as shown in Fig. 15. Now, having riveted your verge, next see to the holes; if they are jewelled, you will have made the pivot to fit the holes; but if brass, *vice versâ*.

FIG. 13.

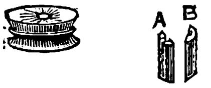

FIG. 14.

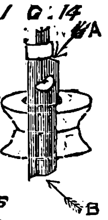

FIG. 19.

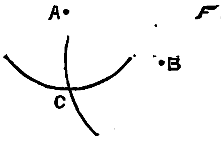

FIG. 15.

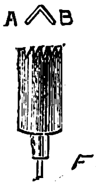

FIG. 16.

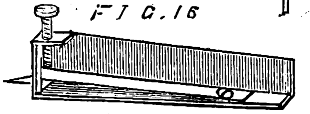

FIG. 17.

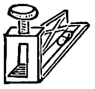

FIG. 18.

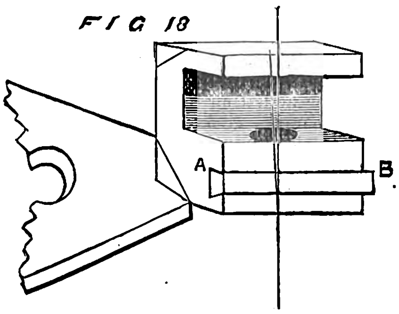

To Put a New Hole in Cockplate (or Bar).—If there is sufficient of the bush left, you may knock it through a little way; file away nearly to the bottom of the old hole; then, with a drill same size as pivot, drill the hole; finish with a bottoming-tool, which should be chisel-pointed, the chamfer a little; if there is not enough bush left, you must fit a fresh one; fit a piece of brass wire, which should be cut off close from the inside; make the hole a little out of the centre, so that by turning the bush round you can bring the verge upright; the bottom hole is done in the same way, only cut off close on the outside, or else it may rub on centre-wheel.

To put a hole in potence slip, you can fit a bush (or bouchong) 1s. per 100. Make the old hole large enough to hold bush firm with a small broach. If your escape is not deep enough on verge, or, as I should say, got too much drop, it is then necessary to file away the face of the potence. This should be done with great care. A good fine file that will cut without any pressing. Fancy you are trying to file the hole, and in this way you will get a flat surface. Some would chamfer the hole, but I do not agree with that, as the potence will have eventually to be cut. In some cases a new slip is necessary, and in such cases I should advise my readers to put one. They will find that it is easier to put a new one than "*make* the old one do"; in fact, makeshifts in any part of a watch will not do—it is sure to take a long time, and is only a makeshift when it is done. Therefore, throw away the old slip, and fit a new one; but before you throw it away you must get position of the hole, which is done with a simple tool, 16 and 17. The screw B raises or lowers point A. You lay your tool on plate, to which you have fixed potence and follower, and take heights of hole; thus you secure the height. The hole should be in a line with the top and bottom hole. Now try your drop, which, if it is not right, you must adjust with the potence slip. If there is too much drop at *top*, you must move the slip from A to B; if at bottom, *vice versâ*. By making a mark across the face of the potence, you will be able to see how much you move it. There should be a little more drop at bottom than top, just enough to discern. This may not seem right in theory, but you will find it right in practice. I can explain if required.

Hairspring.—Practice only can manage a hairspring; so I should advise you to get an old one and practice upon it. There are tweezers made for the purpose. If you want to shift the collet after it is on the verge, you must insert the head of a small drill in the slot of the collet, then by gradually turning the drill you will open the collet, and then you can move it which way you like. If you have got a hairspring that lies uneven, you must put it on a blue-pan and blue it. When you take it from the pan it should be flat; but the less you mess hairsprings about the better. A hairspring is not much use after it has been crippled.

Now I think we have done with the escapement, and will go on with the other parts.

Pillar Plate, Fig. 1.—Always try the pillars; and if you find one loose, place one end on a piece of lead and rivet tighter. No screw should protrude through the inside of the plate or steady pins, or anything that is likely to interfere with the wheels between the plates.

Making a New Hole.—First get the position of the old hole, as follows. Fig. 19, C (where the lines cross), is the old hole; first make two dots, A and B, with your centre-punch, and draw the lines indicated with your compass. Now drive out the old bush, fit in a fresh one—that is, file up a piece of good brass wire, press it firmly into the hole, and cut off close to the *inside*, and about ¼in. from the outside. Now take your compass again, and make the diagram perfect, which have been partly destroyed by the removal of old bush. Now drill a small hole at C, exactly where the lines cross one another, put in the wheel with the other wheels, and try the depth, when, by taking hold of the ¼in. left for this purpose, you can put the wheel deeper or fleeter, as you require it. Now break off the ¼in., which has been previously nearly cut off, with an old knife.

(*To be continued.*)

IRIS-DIAPHRAGM FOR VARYING THE APERTURE OF MICROSCOPE OBJECTIVES.

SOME years since, Dr. Royston-Pigott applied an Iris-diaphragm behind the objective for reducing the aperture of objectives, in support of the view which he was then advocating that wide-aperture objectives produced confused images.

The editor of the *Northern Microscopist* has recently suggested the use of such a diaphragm to enable penetration to be obtained with wide-angled objectives of different apertures. Fig. 1 is a side view of the apparatus, as made by Mr. C. Collins, of Great Portland-street, and Fig. 2 a front view. The upper end in the former Fig. screws into the microscope tube, while the lower receives the objective. The diaphragm is opened or shut by sliding the lever projecting at the side. The partial closing of the diaphragm does not, of course, contract the *field*, but diminishes its brightness by obstructing the passage of a greater or less part of the cone of rays.

Fig. 1.

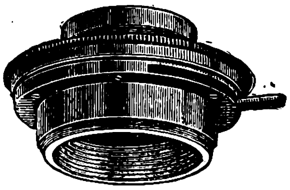

Fig. 2.

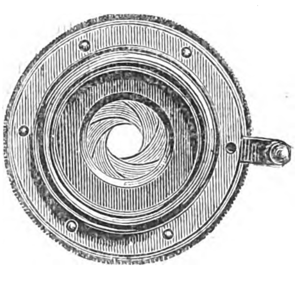

In some remarks on the use of the apparatus it is pointed out* that it shows the value of wide apertures for good definition, for if a preparation of the proboscis of the blow-fly be observed with an inch objective having an air angle of 30°, the view is superb, the pseudo-tracheal markings come out well-defined and sharp; but close the shutter until an angle of 14° or less is obtained, and examine again, when it will be found that the definition is not nearly so good, while there is more penetration, the whole of the pseudo-tracheal tube being observed under one focussing. While in this condition, the eye being still applied to the tube, open the shutter to its full extent, and the effect of wide aperture will demonstrate itself.

"Perhaps the best object to show the amount of penetration possessed by objectives of low angle, may be found in the micro-fungus, *Myxotrichum deflexum*, or *M. chartarum*, observed under the 1in. objective. The former object consists of little patches of grey downy balls, from which arise a number of radiating threads, furnished with a few opposite and deflexed branches. Under an inch objective of 30° air angle, but few of these branches can be seen under one focussing, the remainder being enveloped in a haze of light; but if a central layer be focussed, the simple closing of the shutter will suffice to bring the superior and inferior layers into view, though, of course, the image is not so bright and well defined as before."

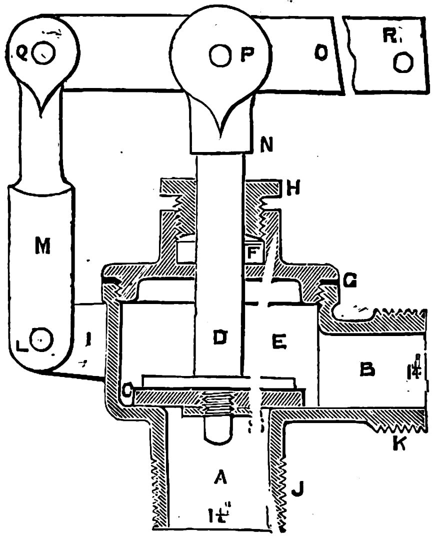
PRACTICAL NOTES ON PLUMBING.—XXIX.*

By P. J. Davies, H.M.A.S.P., &c.

Stool-Valves.

Fig. 148 shows the stool-valve with stuffing-box, for fixing under the seat of a w.c., attached to the spreader. I gave a full description of it last week.

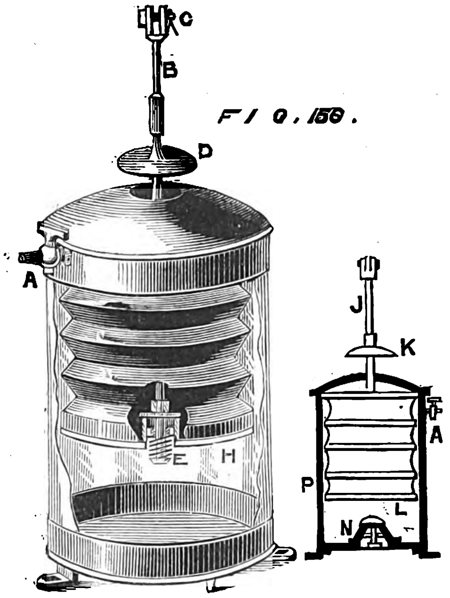
FIG. 148.



The Bellows Regulator.

So far as reliance is concerned, this closet-valve regulator is unquestionably the best yet introduced; it is simply a lantern bellows, with copper, or other metal casing, as shown at Fig. 156. P is the casing, L the bellows fixed round the top of the casing; the action is, that the raising of the handle N, Fig. 84 (whereon is fixed a spur), brings up the valve-lever N, Fig. 142, and, with it, the rod of the bellows J, or B, Fig. 156. When the handle is dropped, the apparatus is prevented from falling back quickly by reason of the bellows expanding and displacing the air from within the casing, in proportion to the opening of the regulating-tap, AA. It is not unusual to make these bellows to take in the air through the regulating-cock, instead of expelling it; but, under any circumstances, the same end is attained, that is to say, the lever with valve is allowed to close slowly.

FIG. 156.



Oil Brass Closet-Regulators.

Thoroughly practical men, I am sure, will agree with me when I say that I cannot recommend the regulators, inasmuch as where oil is used as a lubricant, it very soon becomes cloggy, and even glycerine will not be found a good lubricant for any length of time, though it is far better than common oil, more especially in the winter season. A, Fig. 157, is the cylinder, within which the piston, D, works. On raising this, air gets below J, and, when the lever or rod is depressed, the bucket J of the piston expands, and so keeps the valve-lever from suddenly falling; but, by opening the regulating-screw C, the inclosed air is released, and, in proportion to the opening, so the piston, with the closet-valve, is allowed to fall and close the seating. This kind of regulator is shown at Fig. 157A, as generally fitted to a stool-valve on an iron frame, MN, in damp places, where the bellows are likely to decay. J is the regulator. In such situations glycerine (or quicksilver) should be used, instead of sweet oil.

FIG. 157.

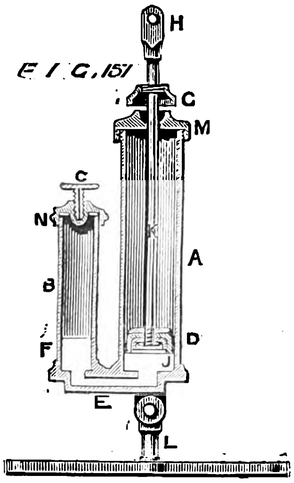


FIG. 157A

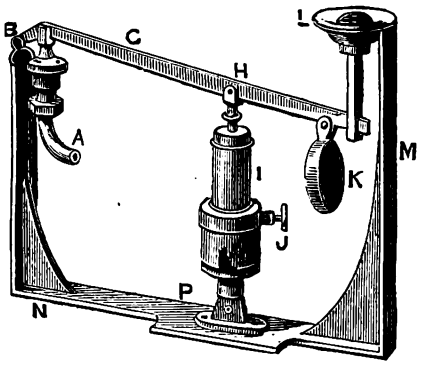

Cottage Closet-Valves with Diaphragms.

These valves will be shown at Figs. 158 and 159, which we are compelled to hold over till next week. Fig. 158 is the supply-pipe to come from below and be connected at I, which, in many instances, will save a bend, as also some lead piping. Fig. 159 shows the valve, having the inlet on top at I; this will be found very suitable in cases when the pipe has to be run down the left-hand side of a w.c., and will also save a double bend. These closet-valves, however, as generally made, are very objectionable, for exemplification of which see Fig. 160; this is the cottage closet-valve, with diaphragm in section. I is the inlet, F the outlet, and M the brass part of the valve, to which is fixed the indiarubber X. This valve, in order to keep it perpendicular to the seating, has a guide-nut, T, having spurs or feathers, see P Q R S, also N T. This blocks the water-passage, and often to the extent of three-fourths of the water-way, so that it is simply absurd to use an inch valve in connection with an inch pipe. Such a valve as the one illustrated should, therefore, never be used. These valves though, be it understood, are capable of improvement; for instance, instead of using the feathered nut, as shown in the diagram, and commonly made for these valves, let the top-plate V, just where the spindle enters at W, be made, as shown, longer than those at Figs. 158 and 159, and so let this guide and steady the valve. There is no reason why this should not be done.

Single Diaphragm Waste-Preventing Valves.

Fig. 160A represents one of the first single diaphragm waste-preventing valves made by my late firm at Hornsey and King's Cross; the same have been made to a very great extent, on account of their extreme simplicity. They are suitable for a servant's closet, or may be fixed over a service-box for either valve or pan-closets. G is the seating to be soldered to the bottom of the cistern, and over the down-pipe I, or this may be connected by nut and screw to the cistern. M is the pull-up spindle for attaching the copper wire to D (which may be made to work through a stuffing-box at P), the spindle for actuating the flexible diaphragm L. This diaphragm is fixed at H to the ring P, which is also connected to the valve-plate B. At B is a small regulating-hole, for the purpose of allowing the descent of the valve when the spindle is being held up.

FIG. 160.

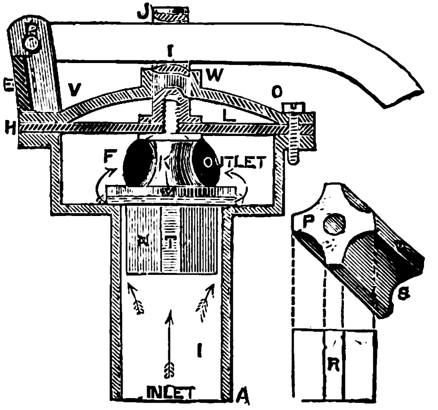

FIG. 160A.

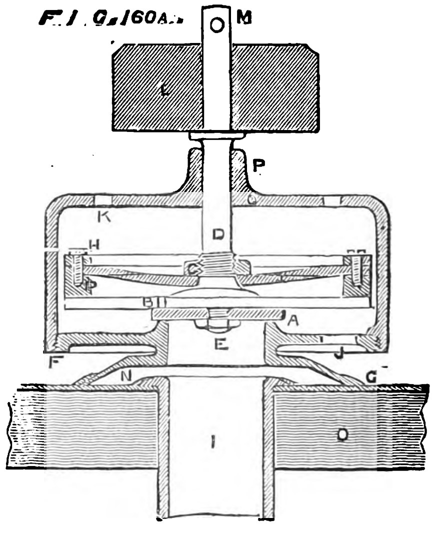


The action is that, on pulling up the spindle D, it brings up the flexible diaphragm, and, with it, the outlet-valve A; but, as the top, Q, limits the amount of lift to both diaphragm and valve, the flexibility of the diaphragm allows the valve to descend slowly, and so cuts off the water from above and below the valve seating. This valve has been made to work under the closet seat, and is done by making the casing Q watertight with a stuffing-box, and by cutting a thread either at J or any other part of the valve-casing. Of course, in this latter case the spindle M is best worked with a lever.

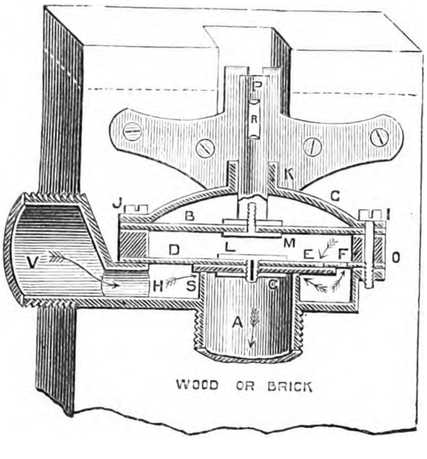
Diaphragm Waste-Preventing Closet Cottage Valves.

Fig. 161 illustrates a double diaphragm waste-preventer valve. It has an improvement over that shown in Fig. 160, inasmuch as the feathered nut is here dispensed with, and the spindle made to work through a guide in the top. To understand the action note the following particulars: Suppose all to be full of water, i.e., between D, H, A, V, &c., V to be the inlet, and A the outlet; then pull up the spindle P of the top diaphragm B; this, by reason that the water is between the two diaphragms will, so to speak, suck up the other diaphragm D, thereby opening the valve attached, when, of course, water will run to the w.c.; but by reason that there is a small hole F in the bottom diaphragm, and that this diaphragm has weight, the water will run up through the hole F, and allow the diaphragm D with the valve S to descend slowly, and again cover the seating; this happens notwithstanding that the lever and top diaphragm are being held up.

---

* From the *Building News*. All rights reserved.

FIG. 161.



Suppose such an action to have taken place, and drop the lever, the top diaphragm will fall and send out water from between the diaphragms through the small and simple relief-valve E, which opens downward; the arrows indicate the direction in which the water rushes during the time the valve is in action—*i.e.*, during the upward or downward motion.

Double-Action Waste-Preventer Valves.

The Metropolitan and other water company's Acts, especially that dated 1871, has created much agitation and not a little enterprise and inventive talent in the manufacture of water-closet valves, which may very easily be accounted for by reference to the following items in the Act. It will be seen by Clause 21, which I here insert, that the supply of water to closets is limited. It says:—

"Every water-closet cistern or water-closet service-box hereafter fitted, in which water supplied by the company is to be used, shall have an efficient waste-preventing apparatus so constructed as not to be capable of discharging more than two gallons of water at each flush." But it does not make any stipulation as to the number of times you may repeat the flushes. Here is the result: by referring once more to Fig. 147 you will observe the valve-closet, and above it the cistern with the double-action waste-preventing valve, capable of discharging the two gallons twice over, but at different intervals. These after-flush valves should be thoroughly understood by every plumber, for the reason that, like most other water fittings, their good or bad working will, to a great extent, depend upon the treatment they receive from him. Every builder or master plumber should bear this well in mind, as my experience has taught me that half the best sanitary fittings (more especially valves) are spoilt by the clumsiness or carelessness of unskilled workmen.

Fig. 162 is a section of one of the Double-action Water-waste Preventers (for the method of fixing and elevation see Fig. 147) for fixing in a cistern under water. B is the tinned seating, to be wiped over the mouth of the down-pipe leading to the w.c., as at 49, Fig. 147. W L, Fig. 162, are the valve-seatings; I and X are the suckers, and JJ the sucker-plates; RR the regulating-holes, G T the casing.

Next refer to Fig. 163, which illustrates a valve similar to Fig 162, the difference being that Fig. 163 is for fixing under the seat of a w.c., and consequently the body, shell, or casing must be varied from that shown at Fig. 162, but Fig. 163 may be fixed and used either in or out of a cistern; that is to say, the outlet A of the valve may be screwed to the bottom of the cistern with an ordinary fly or back-nut, or it may be screwed into a pipe; this, though, only under exceptional circumstances, as the cost of the valve at Fig. 163 is nearly double that of 162, in consequence of the extra strength required for the body-shell or casing, and the extra work for stuffing nuts, boxes, &c.

FIG. 162.

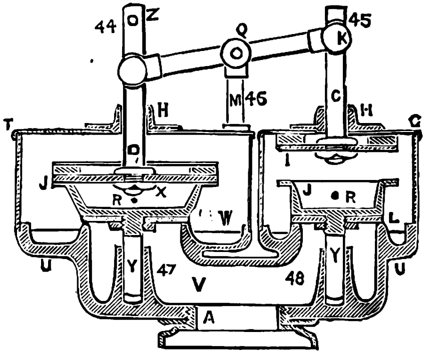


FIG 163

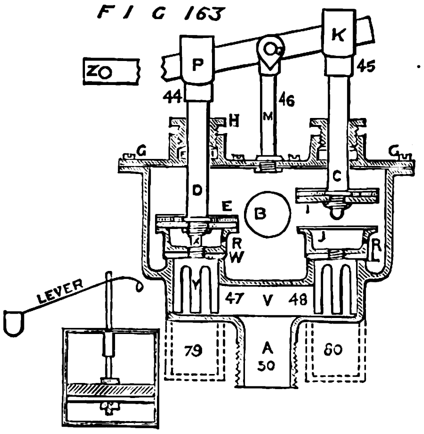

The valve W L, when fixed to work under heavy pressure, is made with loose, retarding pistons, and chambers, as shown by the dotted lines at 79 and 80; this is nothing more than a water-cushion or cataract, as shown at K, Fig. 153. The real use of the water-cushion in Fig. 163 is to prevent the slamming of the valves; whilst the use of the same in Fig. 153 is to keep the valve open for a particular period. It also acts as a preventative to slamming. If a flexible diaphragm is used, as illustrated at L, 160 A, or a ball connected to the valve-dish, the valve cannot drop off, and the valve consequently falls slowly, accordingly as the ball or diaphragm may expand, open, or fall.

(*To be continued.*)

ON COMETS.*

By William Huggins, D.C.L., LL.D., F.R.S.

At the present moment there is no consensus of opinion as to the nature of comets. But within the last few years, from two opposite directions—from the use of the spectroscope and from mathematical investigation applied to the periodical displays of shooting stars—much knowledge has been gained of their nature, though there are still many points on which we can only speculate. It is my purpose this evening to give chief prominence to the new knowledge which these two methods of research have placed within our reach, and to distinguish as clearly as may be possible between what we know about comets and what is not more than speculation.

To carry out this purpose we must first study carefully the phenomena which have to be explained, namely, the essential appearances and changes which comets present during their approach to the sun, at the time that they are visible to us.

It is not necessary here to describe in detail the more purely astronomical side of the subject. It will be sufficient to say, in two words, that some comets have become permanent members of our system, while others probably visit us once only, never to return. It depends upon a comet's velocity whether its course should be a hyperbola, a parabola, or an ellipse. In the latter case only can it become a permanently attached member of our system. If the velocity of the comet when at the earth's distance from the sun exceeds 26 miles a second, the comet must go off into space, never to come back to us. If the comet is going less swiftly, its path will return into itself, and it will visit us periodically after longer or shorter wanderings. In the case of many comets, including the brightest comet of last year, their velocity is so near the parabolic limit that it is scarcely possible, from observations made in the small part of their orbit near the sun, to be quite sure whether they will return to us or not. A number of comets, chiefly small ones, are certainly periodic, and of some comets several returns, true to the calculated time, have been observed.

The small portion of the comet's life during which we are able to study it is quite unlike its ordinary humdrum existence. It consists of the short period of extreme excitement into which it is thrown by a more or less near approach to the sun—a state of things which is accompanied by rapid and marvellous changes, often on a stupendous scale.

1. *The nucleus.* With the aid of a telescope, in the heads of most comets a minute bright point may be found. This apparently insignificent speck is truly the heart and kernel of the whole thing—potentially it is the comet. It is this small part alone which conforms rigorously to the laws of gravitation, and moves strictly in its orbit. If we could see a great comet during its distant wanderings, when it has put off the gala trappings of perihelion, it would be a very sober object, and consist of little more than nucleus alone. It is only this part of the comet which can have any claim to solidity, or even appreciable weight. Though many of the telescopic comets are of extremely small mass, nucleus included—so small, indeed, that they are unable to perturb such small bodies as Jupiter's satellites—yet in some large comets the nucleus may be a few hundred miles in diameter, and may consist of solid matter. I need not say that the collision of a cometary nucleus of this order with the earth would be fraught with danger on a very wide scale.

2. *The coma.* This appears usually as a luminous fog surrounding the nucleus, and gradually shading off from it. The nucleus and the coma form together the head of the comet.

3. *The tail.* The tail may be considered as a continuation, in a direction opposite to that of the sun, of the luminous fog of the coma. This appendage may be scarcely distinguishable as a slight elongation of the coma, or it may extend half across the heavens, and be many millions of miles in length. The tail may be single, or composed of several branches.

We must now study more closely the cometary appearances as they may be seen when a large telescope is directed to a brilliant comet. I have selected for this purpose the Great Comet for 1858, and I shall exhibit on the screen a series of views of this comet, taken at intervals of a few days. The first set shows the growth, position, and form of the tail, as a whole. The second group represents the more detailed structure and changes of form of the head of the comet, as viewed in a large telescope. These views are, of course, from sketches made at the telescope. Last year several attempts were made to photograph the comet which appeared in June. M. Janssen has kindly sent me a positive taken from the original negative. M. Janssen purposely sacrificed detail in the head of the comet, for the sake of obtaining the structure and form of the tail, exposing the plate for thirty minutes. From a careful examination of several similar negatives, Janssen made a drawing of the comet. Mr. Common, at Ealing, with a fine three-foot reflector of his own construction, also photographed the comet, but his object, different from that of Janssen, was to get the form of the nucleus. For this purpose he gave an exposure of only ten minutes—far too short to obtain an impression of the tail. The comet was also photographed by Dr. Draper, of New York. My own work was confined to the comet's spectrum, of which I shall speak presently.

We may now advance to the consideration of two primary questions:—

1. Does a comet shine wholly by reflected solar light, or has it also light of its own?

2. Of what material is a comet composed?

The spectroscope has furnished us with information on both these points. The first successful application of the spectroscope to a comet was in 1864, when Donati discovered in its light three bright bands. In 1866 I was able to distinguish two kinds of light from a telescopic comet—the one kind giving a continuous spectrum and presumably solar light, and the other a spectrum of three bright bands, similar to those which had been seen by Donati. But in 1868 a great advance was made. The close agreement of measures I took of the bands of the comet *b* of that year with those I had previously taken of the spectrum of certain compounds of carbon led me to compare, directly, in conjunction with my friend Dr. W. Allen Miller, the spectrum of the induction spark in olefiant gas, with the comet's spectrum, in the manner shown upon the screen.

---

* The substance of a lecture delivered before the Royal Institution.

There could be no longer any doubt of the oneness of chemical nature of the cometary stuff with the gas we were using—in fact, that carbon, in some form or in some state of combination, existed in the cometary matter. From that time some twenty comets have been examined by different observers. The general close agreement, notwithstanding some; small divergences, of the positions of the three bands with those seen in the flame spectrum of hydrocarbons, leaves no doubt whatever that the original light of comets is really due to matter containing carbon in combination with hydrogen.

At first, indeed, for certain reasons, I was led to consider this spectrum to be that of carbon itself in the form of gas: a view still held by some physicists; but subsequent researches by several experimentalists on this point appear to me to be strongly in favour of carbon combined with hydrogen.

Last year another advance was made. For the first time since the spectroscope has been in the hands of the astronomer, the coming of a bright comet made it possible to extend this mode of research into the more refrangible region of the spectrum. Making use of the apparatus and arrangements which I employed for photographing the spectra of stars, I succeeded in obtaining a photograph of the spectrum of the head of comet *b*.

A copy of this spectrum is now upon the screen. There is a continuous spectrum which can be traced from about G to beyond K, in which are seen distinctly several of the Fraunhofer lines, G, *h* H, K, and many others. The presence of these lines was crucial, and made it certain that this continuous spectrum was really due to reflected solar light. But there was also present a second spectrum consisting chiefly of two groups of *bright* lines. These evidently were due to the same light which is resolved, in the visible region, into the three bright groups. I regarded them with intense interest, for there was certainly hidden within these hieroglyphics some new information for us. Measures of their position in the spectrum, taken under the microscope, brought out that these groups were undoubtedly the same which appear in certain compounds of carbon. Professors Liveing and Dewar had recently shown that these groups indicate a *nitrogen* compound of carbon, namely, cyanogen. On this view there must be in the cometary matter, besides carbon and hydrogen, the element *nitrogen*.

A few days after my photograph was taken, Dr. Draper succeeded in obtaining a photograph of the comet's spectrum, which appears to confirm mine so far as the bright lines, but does not give the Fraunhofer lines. About the same time that the observations were made on the comet, Professor Dewar succeeded in confirming his results, by the reversal of the groups, employing either titanic cyanide or boron nitride.

The positions and characters of these bands, together with those in the visible spectrum, leave no doubt that the substances, carbon, hydrogen, and nitrogen, and probably oxygen, are present in the cometary matter, and that this light-emitting stuff appears to be essentially of the same chemical nature for all the comets, some twenty, which have been observed up to the present time. Certain minor modifications of the common type of spectrum are often present, and show, as was to be expected, that the conditions prevailing in different comets, and indeed in any one comet from day to day, are not rigidly uniform.

The temperature, the state of tenuity, the more or less copious supply from the nucleus of the gaseous matter, must be subject to continual variation. At times it is probable that the hydrocarbon spectrum is complicated by traces of the spectrum of the oxygen compounds of carbon. These and other possible variations betray themselves to us in the spectrum, by the length of range of refrangibility through which each group can be traced, by an alteration in the position of maximum brightness in the groups, by the relative brightness of the groups, by a more or less breaking up of the shaded light of the bands and the visibility or otherwise of bright lines, by a more or less distinctness of the violet group, and, lastly, by the visibility in the brightest comet of last year of a less refrangible band of the hydrocarbon spectrum which occurs between C and D of the spectrum.*

We must now consider the information about the nature of comets which has come to us from a wholly different source. On almost any fine night, after a short watch of the heavens, we shall see the well-known appearances of "shooting stars." At ordinary times these are small, and appear indifferently in all parts of the heavens; but on certain nights they show themselves in great numbers, and of such brilliancy, as to present a spectacle of much magnificence. On such occasions one remarkable feature presents itself, which is well marked in the diagram on the screen. The meteors all shoot forth from one spot, which is called the radiant point. A little consideration will show that this appearance is really due to perspective, and represents the vanishing point of the parallel courses in which the meteors are moving. Hence we learn that they all belong to an enormous swarm of these bodies which the earth is meeting, and further, we may find the direction in which the swarm is moving relatively to the earth. Now the researches of Olbers, H. A. Newton, and Adams showed that the November shower is really a planetary swarm, revolving round the sun in about 33¼ years. Further investigations of Schiaparelli, Leverrier, and Oppolzer brought out the astonishing result that the path of the November meteors is really identical with that of a comet discovered by Tempel in 1865. Schiaparelli showed further, that another independent group of meteors which appears in August, has an orbit identical with the third comet of 1862. We are thus led to see the close physical connection, and oneness of origin, if not indeed identity of nature, of comets and of these meteors. Now the meteors on these occasions are too minute to pass through the ordeal of ignition by our atmosphere, they are burnt up before they reach the earth, but at other times small celestial masses come down to us, which, there can be little doubt, are of the same order of bodies, and similar in chemical nature. The meteorites we have in our hands contain matter of the same kind probably as that which gives rise to cometary phenomena. These two small meteorites, which fell at Estherville, were kindly sent to me by Professor Newton, as probably good examples of the sort of stuff of which the nuclei of comets are composed. The question arises, Are the revelations of the spectroscope about comets in harmony with what we know of the chemical nature of these celestial waifs and strays?

Meteorites may be arranged in a long series, passing from metallic iron alloyed with nickel at one extremity, to those of a stony nature, chiefly silicates, at the other. In meteorites more than twenty of the elementary bodies have been found, including hydrogen, carbon, and nitrogen, which the spectroscope has shown to be in comets. It may be, however, that in the sun's action on comets, we have to do not with the decomposition of the cometary matter, but with the setting free of gases occluded within the meteoric matter, forming the comet's nucleus. If the meteoric matter were decomposed, we should expect a more complicated spectrum.

Some years ago, in conjunction with my friend, Professor Maskelyne, I examined the spectra of certain meteorites, and obtained in several cases a spectrum similar to that of comets. Some meteorites, like that of Bokkveldt, contain a large percentage of hydrocarbons. Professor Vogel has recently experimented in the same direction, and finds that the gas which comes off from the meteorite he used gives a hydrocarbon spectrum mixed with that of carbonic oxide, and under certain conditions the spectrum of hydrocarbon predominates and becomes almost exactly similar to that of comet *b* 1881. We are at a disadvantage in one particular, for we cannot get at meteorites as they exist in celestial space, but only after superficial ignition in passing through the air.

The experiments hitherto made throw but little light on the question, whether cyanogen ready formed is present in combination or otherwise in the comet, or whether it is formed at the time by the interaction of carbonaceous and nitrogenous matter. In the latter case we should have to admit a high temperature, which would be in favour of the view of an electric origin of the comet's light. Professor A. Herschel and Dr. Von Konkoly have pointed out that the spectra of the periodic meteors are different for different groups. I may also mention that Captain Abney considers that he has evidence of hydrocarbons in the outer portion of the sun's atmosphere.

We have now advanced to the extreme boundary of the solid ground of our knowledge of comets. Before us lies the enchanted region of speculation. Without being too venturesome, we may well consider a few points which may explain more in detail some of the phenomena of comets. Of whatever nature we may regard the tremendous changes which take place in them to be, we must certainly look for the primary disturbing cause to the sun. Is the solar heat sufficient to account directly for the self-light of comets, or does it act the part of a trigger, setting free chemical or electrical forces? On this point of the sufficiency of the solar radiation we must not look to the few cases of exceptionally close approach to the sun, but to the more average distance of comets at perihelion. Professor Stokes has suggested that some results obtained by Mr. Crookes may throw light upon this question. He concluded from his experiments that in such vacua as exist in planetary space the loss of heat, which in such cases would take place only by radiation, would be exceedingly small. In this way the heat received from the sun by the comet would accumulate, and we should get a much higher temperature than would otherwise be possible. In this connection may be mentioned the remarkable persistence of the bright trains of meteors in the cold upper air, which sometimes remain visible for three-quarters of an hour before the light fades out by the gradual dissipation of the energy.

I need hardly say that the enormous tails of bright comets, many millions of miles in length, cannot be considered as one and the same material object, brandished round like a great flaming sword, as the comet moves about the sun. It is but little less difficult to suppose that the cometary mass is of so large an extent as to include all the space successively occupied by the sweep of the tail at perihelion. On the material theory we seem to be shut up to the view that the tail is constantly renewed and reformed, either by matter streaming from the nucleus or in some other way. But this view involves velocities far greater than the force of gravitation can account for. Let us consider the order of the phenomena. Under the sun's influence, luminous jets issue from the matter of the nucleus on the side exposed to the sun's heat. These are almost immediately arrested in their motion sunwards, and form a luminous cap; the matter of this cap then appears to stream out into the tail, as if by a violent wind setting against it. Now, one hypothesis supposes these appearances to correspond to the real state of things in the comet, and that there exists a repulsive force of some kind acting between the sun and the gaseous matter, after it has been emitted by the nucleus. On this hypothesis the forms of the tails of comets, which are usually curved, and denser on the convex side, admit of explanation. Each particle of matter of the tail must be moving in a curved course, under the influence of the motion it originally possessed, combined with that of this hypothetical repulsive force. But in the form which the tail assumes for us we have not only to consider the effect of perspective, but also that the comet itself is advancing, so that the visible tail is due to the portion of space which at the time contains all the repelled matter, each particle describing its own independent orbit, and reflecting to the eye the solar light or giving out its own light, as the case may be. The value of the repulsive force which would be necessary on this theory has been investigated by Bessel, Peirce, and others. Recently Bredichin has investigated the curvatures of the tails of a number of comets. According to him, they fall into three classes, each type of curve depending upon a different assumed value of the repulsive force. This leads to another point, namely, the secondary tails which are often present. Some of these appear to be darted off with an energy of repulsion so enormously great that the original motion of the nucleus tells for very little, and hence the secondary tail is but slightly curved, or even is sensibly straight. Again, if we take the hypothesis that this repulsive force, of whatever character it may be, varies as the surface, and not, like gravity, as the mass, substances of different specific gravity would be differently affected and separated from each other, and these secondary straight, or nearly straight, tails would, on this view, consist of the lightest matter.

On this hypothesis a comet would suffer of course a large waste of material at each return to perihelion, as the nucleus would be unable to gather up again to itself the scattered matter of the tail; and this view is in accordance with the fact that no comet of short period has a tail of any considerable magnitude.

A theory, based on chemical decomposition, has been proposed by Professor Tyndall; but as this view has been illustrated here by the eloquent author himself, I will not now enter upon it.

A different view of the whole matter has been suggested by Professor Tait. He supposes, not the nucleus only, but the whole comet, to consist of a swarm, of enormous dimensions, of minute meteoroids, which become self-luminous at and about the nucleus, in consequence of the impacts of the various meteoric masses against each other, giving rise to incandescence, melting, the development of glowing gas, and the crushing and breaking up of the bodies into fragments of different sizes, and endowed with a great variety of velocities. She tail he conceives to be a portion of the less dense part of the train illuminated by sunlight, and visible or invisible to us, according not only to circumstances of density, illumination, and nearness, but also of tactic arrangement, as of a flock of birds under different conditions of perspective, or the edge of a cloud of tobacco-smoke.

On this hypothesis we should expect to find a more complicated spectrum, and the spectra of comets to differ greatly from each other.

There seems to be a rapidly-growing feeling among physicists that both the self-light of comets and the phenomena of their tails belong to the order of electrical phenomena. One of the most distinguished of the American astronomers wrote to me recently: "As to the American views of the self-light of comets I cannot speak with authority for anyone but myself, still I think the prevailing impression amongst us is that the light is due to an electric, or, if I may coin the word, electric-oid action of some kind." Here I confess I tread most cautiously, for we have no longer any stepping-stones of fact on which to place our feet. I am ready to admit that the spectroscopic evidence, especially that furnished by the photographs of last year, favours, though it does not necessarily demand, the view that the self-light of comets is due to electric discharges. I do not attach much importance to the fact that the bright groups in the visible spectrum of comet *b* agreed with those of the so-called "flame spectrum," for the reason that the same spectrum may be obtained from the induction-spark, when suitable arrangements are used to make the discharge one of comparatively low temperature.

---

* For these reasons measures of these bands should be considered as strictly applicable to the particular comet at the time of observation only, and not necessarily as applicable to other comets.

As we are now fairly on the wide ocean of speculation, I need not say that the precise modes of application of the principle of electricity which have been suggested are many. Broadly, they group themselves about the common idea that great electrical disturbances are set up by the sun's action in connection with the vaporisation of some of the matter of the nucleus, and that the tail is matter carried away, possibly in connection with electric discharges, in consequence of the repulsive influence of the sun, which is supposed to be in a state of constant high electrical potential of the same name. Further, it is supposed that the luminous jets and streams and caps and envelopes belong to the same order of phenomena as the aurora, the electrical brush, and the stratified discharges of exhausted tubes. Views resting more or less on this basis have been suggested by several physicists, and, in particular, have been elaborated at great length by Zöllner, who endeavours to show that on certain assumed data, which appear to him to be highly probable, the known laws of electricity are fully adequate to the explanation of the phenomena of comets.

All the theories we have considered assume that the bright lines seen in the spectra of comets indicate heated luminous gas. An alternative hypothesis has been suggested by Professor Wright, and especially by Mr. Johnstone Stoney, who considers that the compound of carbon vapour is opaque in reference to the particular rays which appear as bright lines in consequence of sending back to us the sun's rays falling upon the vapour. Further, he considers the phenomenon to be of the order of phosphorescent bodies, and he states that the conditions existing in the cometary gas are such as will eminently promote phosphorescence, and therefore visibility, in presence of a luminary.

ELECTRIC LIGHTING BY INCANDESCENCE.

ON Friday last Mr. Swan lectured at the Royal Institution on the incandescent system of electric lighting, and, in the course of his remarks, gave the following interesting details:—He thought he could fairly say that the difficulties encountered in the construction of incandescent electric lamps had been conquered, and that their use was economically practicable. They knew, by actual experiments, that continuous heating to a fairly high degree of incandescence during 1,200 hours did not destroy a well-made lamp. What the utmost limit of a lamp's life might be they did not know. Probably it would be an ever-increasing span; as, with increasing experience, processes of manufacture were sure to become more and more perfect. Taking it, therefore, as fully established that a cheap and durable lamp could now be made, the further question was as to the cost of the means of its illumination. The cost of producing light by means of electric incandescence might be compared with the cost of producing gas-light in this way: 2cwt. of coal produced 1,000 cubic feet of gas, and this quantity of gas, of the quality called fifteen-candle gas, would produce 3,000 candle-light for one hour. But besides the product of gas, the coal yielded certain by-products of almost equal value. He would, therefore, take it that they had in effect 1,000 feet of gas from one cwt. of coal, instead of from two, as was actually the case. The one cwt. of coal would give fifty horse-power for one hour. Repeated and reliable experiments showed that they could obtain through the medium of incandescent lamps at least 200 candle-light per horse-power per hour. But as there was waste in the conversion of motive-power into electricity, and also in the conducting-wires, he made a liberal deduction of 25 per cent., and took only 150 candle-light as the net available product of one horse-power. For fifty horse-power, the produce of one cwt. of coal, they had then 7,500 candle-light, as against 3,000 candle-light from 1,000 feet of gas. That was to say, two-and-a-half times the amount of light which the gas from the same quantity of coal was capable of producing. There remained, however, an allowance to be made to cover the cost of the renewal of lamps. Whether by the method of multiple arc, which necessitated the multiplication of electrical stations, or by means of the simple series or of secondary batteries connected with each other from house to house in single series, the lamps being fed from these in multiple arc, he was quite satisfied that comparatively with the distribution of gas, the distribution of electricity was sufficiently economical to permit of its practical application on a large scale. As to the cost of laying wires in a house, he had it on the authority of Sir William Thomson, who had just had his house completely fitted with incandescent lamps, that the cost of internal wires was less than the cost of plumbing in connection with gas-pipes. Referring to the use of carbon as the wick of an electric lamp, Mr. Swan pointed out that excellent carbon filaments could be produced from the bamboo, and also from cotton thread treated with sulphuric acid. The sulphuric acid treatment effected a change in the cotton thread similar to that which was effected in paper in the process of making parchment paper. He exhibited an example of a carbon filament produced from parchmentised cotton thread. The filament, he said, was not more than the ·01 of an inch in diameter, yet a length of three inches, having therefore a surface of nearly the one-tenth of an inch, would give a light of twenty candles when made incandescent to a moderate degree.

GLYCERINE FROM SOAP LYES.

THE following method of extracting glycerine from soap-lyes has been patented by Dr. F. Versman of New Charlton. So many uses have been found for glycerine of late years, that it has been gradually rising in price, and as a querist points out on p. 19, it is now obtained from what are known as the waste products of the soapworks. The following notes will partly answer the query No. 46298. The object of Dr. Versman's invention is the recovery of glycerine from soap-lyes, and its more or less complete separation from the accompanying salts, chiefly chloride of sodium, carbonate of soda, and caustic soda. He separates a large percentage of these salts by simply boiling down the soap-lye and raking out the salts as they become insoluble; he then allows the concentrated solution to cool, after which carbonic acid gas is passed through it until the whole of the carbonate and caustic soda is converted into bicarbonate of soda, which is much less soluble in glycerine than either the carbonate of soda or the caustic soda, and may readily be removed by filtration or other convenient means. The liquid from which the bicarbonate of soda has been removed is rich in glycerine, but it still retains sensible quantities of chloride of sodium and other salts, the presence of which may act injuriously in the subsequent application of the glycerine to certain purposes. These salts the patentee separates by submitting the liquid either hot or cold to the process of osmose in an apparatus known as the "osmogene," such as is used in the separation of saline compounds from solutions of beet-root sugar; by this process nearly all the salts are separated from the glycerine; but as the latter becomes diluted with water it is concentrated by evaporation, when it will be ready for the market as crude glycerine. Instead of commencing the treatment by boiling down the lye, carbonic acid gas may be passed through the original soap-lye, or, if preferred, the use of carbonic acid gas may be dispensed with, but the patentee finds the most convenient and economical way is to first reduce the bulk of the liquid by boiling down so as to separate large quantities of the salts, and then to treat the liquid with carbonic acid; the subsequent treatment in the osmogene is essential in all cases.

This osmogene is a modification of Graham's dialyser and consists of 40 or more cells formed by sheets of parchment paper laid flat and connected at the edges all round, the space between each pair of sheets being fully half an inch. Each sheet is supported by a cross piece of wood and a network of string, and the whole affair is about 4ft. long by 3ft. high. Water is sent through alternate spaces, and the substance from which the salts are to be extracted through the others, the water by osmose carrying off the salts and leaving a small quantity of itself in the syrup or other substance.

SHOP WRINKLES.*

Making Chasers with odd Threads-Grooving Taps—Tempering Taps, Reamers, &c.

A FEW years ago I broke a screw on one of my instruments. This necessitated sending the instrument, or part of it, to get a new one fitted—which would involve the loss of at least six or eight weeks' time and heavy expense.

I had hunted in all of the jewelry, gun and blacksmith shops for a screw plate with the right number of threads, but, of course, I failed to find one. There was no screw-cutting lathe in the vicinity on which I could cut a screw, or make a hob with which to cut a chaser. Under these circumstances, it became necessary to originate a screw; and for the benefit of others, who may some time be similarly situated, I will tell how I managed.

I found a jeweller who offered me the use of a small hand lathe with a slide rest, the feed screw of which was, I believe, 14 threads to 1in. The screw I desired to cut was an odd number—47, I think. The problem I had to solve was how to produce a screw of 47 pitch from one of 14 pitch, without gears, and this is how I did it: I first turned and filed up a milling cutter about ⅓in. diameter, the edge of which I made of the same shape as the thread on the broken screw. I then took a strip of thin brass, drew a straight line through the centre, took a pair of sharp-pointed dividers, setting the points about ⅓in. apart, and marked off 47 points along the line on the brass strip, prick-punching small holes at each point. I cut off each end of the strip a little over 1-6in. beyond the end holes, bent the strip in the form of a hoop, and fitted the ends squarely together until the two end holes were brought the same distance apart as the others. I then wired the ends together and soldered them with silver solder. I next fitted a wooden wheel on a flange in place of the feed handle of the slide-rest, placed this wheel in the lathe, and turned it down until the hoop fitted snugly. I now had an index divided by 47 true enough for the purpose. I then forged a blank chaser, fastened it in the tool post of the slide-rest, placed my cutter in the lathe, and commenced by milling a groove in the end of the blank chaser to the depth of one thread, screwing the cross-feed up to the cutter, and marking the position of the handle. I then backed up the cross-feed, and advanced the feed-screw 14 holes on the index, and milled another groove by screwing up the cross-feed to the same point as in the first cut, bringing the handle to the position marked when milling the first groove, and so on till I grooved the end of the blank across its whole face. I then filed up the chaser, so as to give the proper rake or slant to the teeth, hardened it and did the job, making the required screws with my improvised chaser, a perfect fit.

Any required chaser can be easily made in this manner, the rule being to make an index, having same number of holes as the required screw has threads to one inch, and advance it the same number of holes as the lead screw has threads to one inch; or, when both numbers are divisible by same number, make a fraction, the numerator being the number of threads in the lead screw, and the demoninator the number of threads in the required screw; then reduce to its smallest demoninator. For instance, the lead screw has 12 threads, and it is required to cut 48; then as 12/48 = ¼, you can make an index of four holes, and advance the screw one hole on the index.

I believe the way to groove taps is to make spiral-flutes like a twist drill, only giving less twist, making the flutes with circular section. Small taps up to say ½in. diameter, I file up in the vice with 3 flutes. I use for this purpose a drill file, or a round file. By this method of fluting you can give full stroke to the file, and finish quicker than you can rig up to plane or mill them with the ordinary straight flutes. Any one using this form of tap for the first time will be surprised at the ease with which it cuts, if otherwise properly made.

I have found by experience that there are only a few machinists who can harden and temper such tools as taps, fluted-reamers, &c., and do it properly. They sometimes burn the steel, spring the tool, or crack it in hardening, or temper it so unevenly that it will come out with all the colours of Jacob's coat. I will tell how I do it, and if any think it better than their method they are welcome. There is no patent on it, neither do I claim it as original. I expect a great many mechanics will say, "Who don't know all that," &c. Some may have even a better method. If I have many tools to temper at one time, I use a lead bath. I heat the tools only sufficient to harden, and if heated in an open fire, I use hard soap to prevent oxidation. With some steels which require a high heat to harden, I have found the use of a paste made of prussiate of potash and salt, dissolved in stale beer and thickened with flower, of advantage. The tool should be heated perfectly even, not too quickly, and still it should not soak in heat too long. Experience must be the only guide on this point. After it is properly heated I quench it in a bath of salt brine containing prussiate of potash and corrosive sublimate, acidulated with sulphuric acid. This solution should have the chill taken off so that the temperature is about 50° to 60° F. I don't say that I know this solution is better than pure water, but I have always had better luck (if that is the right word) with it than with pure water. I keep the tool perfectly straight, without motion side ways, and after dipping quickly to a

---

[*] By G. B. FOOTE, in *American Machinist*.

point above where I desire to harden it, then dip very slowly, and raise and lower it slowly for a distance of an inch or two. After the shank has cooled down below a red heat, I cool off by dipping its whole length. After this I polish so as to give a bright clean surface, then wipe it all over with an oily rag or waste, to give a very thin film of oil all over the surface (lard or sperm oil—not mineral). I then heat to a red heat an iron ring or tube of sufficient weight to retain heat, and of sufficient length to take in about half or two-thirds of the length of the hardened portion of the tool. The hole should be of a size so that the tool when placed in the centre will be an inch or so from the hot ring or tube. Insert the tool in the hole, moving it slowly back and forth and turning it around until it takes on the desired colour.

For a ½ in tap or reamer, a piece of 2in. or 2½in. gas pipe, about 3in. long, answers a good purpose. Other tempering sleeves can be made of old pulley hubs, or other pieces that can be found in the scrap heap. Draw the temper slowly, and let the tool cool off without quenching in water, and I believe you will have a satisfactory job. These tempering sleeves are excellent for drawing the temper on many other tools when an even temper is desired.

ELEMENTARY LESSONS IN DRY PLATE PHOTOGRAPHY.—II.*

Chemicals.

We ought to have enumerated in our last lesson, amongst the necessary apparatus, a small balance such as apothecaries use for weighing out medicines. This should be provided with the usual set of "apothecaries' weights." The chemicals required are as follows:—

Pyrogallic acid 1oz.; ammonia of specific gravity ·880, 3 or 4oz.; bromide of ammonia 1oz.; sulphite of soda 4oz.; neutral oxalate of potash ½lb.; sulphate of iron ¼lb.; citric acid 1oz.; hyposulphite of soda 1lb.; alum ¼lb.; methylated spirit ½ pint; negative varnish a few ounces; bi-chloride of mercury ¼oz.; a couple of books of test papers, one of blue-litmus and one of red-litmus.

The ammonia used in photography is the strongest solution of ammonia which it is possible to make in water at atmospheric pressure. When the stock has been purchased, it is advisable to pour it at once into a bottle holding exactly double the amount of ammonia, and to fill up the bottle with water. If this is not done, the stopper of the smaller bottle may be blown out by the pressure of the liberated ammonia gas when the weather is warm.

Neutral oxalate of potash ought to have neither an acid nor an alkaline reaction; but often that sold as neutral is somewhat alkaline.

Sulphate of iron or "copperas" should be kept—after it is dissolved in water—in a closely stopped bottle.

The alum used may be the ordinary alum sold by grocers, and may be either a potash or a soda alum. As it is intended to be dissolved in water, it should be bought in the form of a powder.

Bi-chloride of mercury is a whitish crystalline substance, and is strongly poisonous. It is commonly known as corrosive sublimate.

The test papers are for discovering whether a liquid such as a solution of any salt is neutral, acid, or alkaline. To use them, proceed as follows. Suppose you have a solution of whose condition as regards acidity or alkalinity you are ignorant. Dip a small piece of the blue-litmus paper into the solution. If the paper changes its colour to red at once, or after a short time, the solution is acid; if no change in its colour takes place, the solution is either neutral or alkaline. In this latter case, dip a piece of the red-litimus paper into it; you will now know its exact condition. If the red-litmus becomes blue, the solution is alkaline; if no change takes place, it is acid.

We give instructions for mixing one or two of what are called "stock solution." These are solutions which may be kept for some time, and which the photographer should always have by him. These we now describe are to be used in the first lesson in development.

No. 1 bottle to be labelled "Solution of Oxalate of Potash" in large letters, so that it may be read in a very dull light. Place the whole half pound of neutral oxalate of potash in a bottle capable of holding from ten to twelve ounces. Fill up the bottle with warm water, place in the cork, and shake. A part, but not the whole, of the white crystals, will dissolve. The liquid will be what is called a "saturated solution"—that is, the water will have taken up as much of the salt as it is capable of doing. When any of the solution is used, the bottle should be again filled up with water, and this may be done repeatedly till all the crystals are dissolved, when more oxalate of potash must be purchased. This solution must be tested in the manner described above to discover whether or not it is alkaline. If it is, enough citric acid must be added to make it neutral or very slightly acid.

No. 2 to be labelled "Sulphate of Iron Solution." Place about a half of the sulphate of iron in a half-pint bottle, and proceed exactly as with the last stock solution. It is very necessary in this case to keep the bottle always full of solution, and well corked, as the oxygen of the air, if it come in contact with the liquid, very rapidly spoils it. The solution should be of a bright green colour. If it becomes red, it is useless.

No. 3 *Ammonia-Bromide Solution. One per cent.*—Weigh out twenty grains of ammonia bromide. Place in a four-ounce bottle, and make up to four ounces with water. The percentage is not exactly correct, but is quite near enough for the purpose.

No. 4. *Alum Solution.*—Place three or four ounces of the alum in a pint bottle. Fill up with warm water. The whole of the alum will probably dissolve, but some of it will be thrown down again as crystals when the solution becomes cold. As long as these last, more water may be added from time to time, as the solution is used. When they are all dissolved, alum must be added.

No. 5. *Fixing Solution.*—Place five ounces of hyposulphite of soda or "hypo" in a pint bottle, fill up with warm water, and shake till all is dissolved.

Common tap water may be used for all these solutions.

ROYAL ASTRONOMICAL SOCIETY.

The March meeting of the Society was held on the 10th inst., at Burlington House. Mr. E. J. Stone, President of the Society, and Director of the Radcliffe Observatory, Oxford, occupied the chair.

Mr. Samuel Jefferson, of 17, Virginia-road, Leeds, and Mr. James Leigh, of Watford House, King's Norton, Worcestershire, were balloted for, and duly elected Fellows of the Society.

Prof. Pritchard read a paper entitled "Notes on M. Loewy's Remarks Relative to the Wedge-Extinction Method of Stellar Photometry." He said M. Loewy urges the inequality of the absorptive power of such specimens of neutral-tinted glass as he has hitherto procured. With respect to the wedge used by me, I have examined its action upon spectra obtained from the sun and from a gas-flame, though I have not yet been able to try it upon a spectrum obtained from the electric light. I find that its absorptive power is very uniform, except in the extreme red, where the light is very faint, so that it is not likely to affect the measures of any stars visible to the naked eye; moreover, relative photometry of coloured light does not lie within the reach of any instrument known to me. That disposes of M. Loewy's first objection. I should not have troubled myself to make photometric experiments with neutral-tinted glass without first finding out whether the absorptive power of the glass was or was not equal throughout the spectrum. Secondly, M. Loewy finds that he cannot rely on a wedge to discriminate differences of light equal to 7 or 8 magnitudes. I reply that, as I use the wedge, no two stars differ greatly in light. It is my practice to contract the aperture of the viewing telescope for the brighter star, as it is not desirable to use very large wedge intervals; but I have found that the wedge is reliable for differences extending through at least 6 magnitudes. The second objection of M. Loewy is, I hope, therefore, disposed of. To show the accuracy of the photometric measures made with the wedge, I have given a table comparing the magnitudes of fifteen stars of the Pleiades group obtained with the wedge, and also as obtained by Prof. Pickering with a photometer of entirely different construction, in which the light of the two stars is brought to equality by means of double-image prisms. The result of the comparison shows that there is an average difference of rather less than one-tenth of a magnitude between Prof. Pickering's measures and my own, which is, I think, very satisfactory, and shows that a great advance has been made on the photometric methods used by Argelander and Weiss.

Mr. Knobel said—I think Prof. Pritchard's results are extremely interesting, but I should like to ask whether he has taken any precautions so as to extinguish the stars rapidly. I have found that if you extinguish the light of a star slowly, the muscles of the eye become strained, and if you strain the eye, you require a smaller aperture to extinguish a star a second time. I would ask Prof. Pritchard whether he has taken any precautions, so as to extinguish the stars rapidly, and whether he takes care that the second measure shall be made with a denser portion of the wedge. With regard to the accuracy which Prof. Pritchard has claimed for his method, it should be mentioned that though the averages may differ from Prof. Pickering's by only one-tenth of a magnitude, I see that there are differences between Prof. Pritchard's separate determinations, which amount to as much as three-fourths of a magnitude; consequently, it can only be regarded as a fortunate chance that the averages agree so closely with the magnitude obtained by Prof. Pickering.

Prof. Pritchard said, knowing the importance of making the observations rapidly, I had the wedge arranged so that it could be moved quickly by hand as well as move slowly by a tangent-screw, and having looked over 1,500 or 2,000 observations I am surprised at the uniformity of the final results. Of course we take the mean, just as they do at Greenwich, with transit observations. You would not expect the interval between all the wires to come out the same. I believe that it would be an exaggeration to say that the individual observations differ on the average by as much as the 1-5th of a magnitude.

Mr. Marth pointed out that Mr. Carrington had described a similar method of determining the magnitudes of stars in Vol. XVII. of the *Monthly Notices.*

The President, in returning thanks to Professor Pritchard, said no doubt if the truth were known a great many things that are described would be found to have been done or thought of before. The great point is, whether useful results are deduced. (Applause).

Mr. Christie read a paper, entitled, "Spectroscopic Results for the Motion of Stars in the Line of Sight obtained at the Royal Observatory, Greenwich." He said, this is the fifth list of such observations which have been published in the *Monthly Notices.* The measures have been made with a half-prism spectroscope, giving a dispersion of 18½ degrees. Since the beginning of 1881 a convex cylindrical lens has been placed in the viewing telescope. Up to the present time the motions of 99 stars have been spectroscopically determined; but the results are, in many cases, still uncertain. It is only to very bright stars that we can apply the method to advantage; in the case of fainter stars, such as are now being included in the list, the observations are necessarily subject to much greater errors; therefore, these results are, in some cases, rather discordant. The individual measures are given, so that anyone can, for himself, form an idea of the relative value of the observations.

Mr. Glaisher read a paper by Mr. Burnham on "A New Method of Bright Wire Illumination for Position Micrometers." Hitherto it has been usual to illuminate the field with faint light, and the wires have been seen as dark objects upon it. The plan pursued by Mr. Burnham is to illuminate the wires. He says the convenience and practical value of this arrangement can only be appreciated by one who has used the old plan and then tried this; a very feeble light is sufficient to illuminate the wires, so that no object which can be seen is now too faint to be measured.

Mr. Neison read a paper entitled "Note on a Term in the Perturbation of the Moon due to the Action of Mars." He said—When at work in the beginning of 1877 on this subject I made a rough calculation, and found a coefficient of several seconds of arc arising from the perturbing effects of Mars. I then communicated the results to the Society, and pointed out that they were only comparatively rough approximations, but that they accounted for an inequality of long period which had been noticed by Sir George Airy, who had pointed out that Hanssen's tables gave places discordant with the observations from 1751 to 1851. Lately a young Frenchman has sent me a paper which he has written as his thesis on obtaining his degree. He had calculated the term with correct accuracy by Delaunay's method, and he finds a coefficient which is exceedingly small; but, like Delaunay, he has not carried the approximations far enough, and he has left out terms as insensible which I think it will be found have considerable value; but I would take the opportunity of remarking that his investigation has been made with very great skill and care, and forms an important contribution to astronomy, although he has not carried it sufficiently far, and I hope that he will undertake the further calculations. I have, however, found reason to modify my original view, and I now find that the coefficient is not as large as I originally believed it to be.

Mr. Knobel read a paper by Dr. Konkoly on "Orbits of Meteor Streams," deduced from observations made in Hungary between the years 1871 and 1880. From the radiant points determined by means of about 5,000 observations of meteors, Dr. Konkoly has only been able to identify two meteor orbits as corresponding with known cometry orbits—viz, with the comets 1854-4 and 1861-1.

Mr. Neison said: This is rather an important paper. If it is correct that out of more than 100 meteor orbits Dr. Konkoly has only been able to identify two as corresponding with cometary orbits, it will show that the connection between comets and meteors is not as close as has been ordinarily supposed, or, if there is such a connection, it would seem that the comets rapidly disappeared, only leaving meteor streams in their track. With all the comets that are observed year after year, it is curious that only two such coincidences should have been made out.

Mr. Christie: There is another alternative, namely, that these meteor streams may indicate coming comets. Schiaparelli pointed out that meteors may be the heralds of comets, as well as the indication of comets that have disappeared.

Mr. Ranyard said: It is possible that Dr. Konkoly means that he has only succeeded in identifying two new comets with meteor streams, in addition to those which were already known.

Mr. Knobel: Dr. Konkoly says that he has only been able to identify two meteor orbits with cometary orbits.

Mr. Ranyard: It must be remembered that most of the comets which are observed do not pass sufficiently near the earth to be observed as a meteor stream; possibly some of these meteor streams may be five or ten million miles in diameter, for the earth takes several days to pass through some of them, but unless a comet passed within that distance of the earth's orbit, we ought not to expect to identify it as a meteor stream.

Mr. Neison gave an account of the new lunar crater, observed by Dr. Klein, in the neighbourhood of Hyginus. He said Prof. Schmidt, of Athens, has recently published his observations of the region, and he has arrived at the conclusion that since the year 1878 the object observed by Dr. Klein has been clear and distinct, and is, in fact, the second most conspicuous object in the whole region, whereas in every one of his observations made previously to that date, he was unable to see any trace of it, and he arrived at the conclusion that here at least we have an unquestionable case of physical change on the Moon. I observed this region myself 25 times between 1871 and 1876, and several other persons observed it up to 1877; no observations appear to have been made of this portion of the Moon, so that we cannot say what happened during that year, but now there can be no doubt that if any observer of experience looks at that region at any time within 36 hours after sunrise, he will not fail to see a great black object. I do not say crater, for it may be a mere physical alteration in the colour of the surface, but after Hyginus, it is the most conspicuous object in that region, and cannot fail to be noticed.

Mr. Bidder said: I should like to ask when was the first recorded observation of this object, and is there any reason to suspect that change is still going on in it?

Prof. Pritchard said: It occurs to me that this is very like the story of our old friend Linné. On one occasion I saw Linné as a small crater, and I rose to fetch another person to vouch for my veracity; but when we came back Linné was gone, and there was a white patch in its place. These changes of appearance may arise from difference of illumination.

Mr. Newall said: I have here a drawing of Linné, which I made in 1875, and I have never seen it since. A few hours makes all the difference in the world in its appearance.

Mr. Neison said: Linné was a small crater, so small that you could hardly see it. No one since 1865 has seen it as it used to be seen before that date. No doubt Linné changes very rapidly in appearance with the illumination; but that is not the case with the great black crater near Hyginus, which can be distinctly seen for 36 hours after it has appeared upon the terminator. Here is an object, not merely visible for a few minutes or hours like Linné, but it is a most striking object, which anybody that is at all used to lunar observations cannot fail to notice.

The following papers were also announced and partly read:—H. C. Russell, "The Transit of Mercury, 1881, Nov. 7th, observed in New South Wales," and "Measures of Double Stars, made at the Observatory, New South Wales"; D. Gill, "Note on the North Polar Distance of the Star Lacaille, 4342"; H. C. Rockwell, "Observations of the Transit of Mercury, 1881, Nov. 7th, made at Honolulu, Sandwich Islands; J. Tebbutt, "Observations of Comet III., 1881, made at Windsor, New South Wales"; J. R. Capron, "Observations of the Lunar Eclipse, 1881, Dec. 5th"; Rev. T. R. Robinson, "Note on the Places of Three Stars in the Armagh Cataloque"; C. Piazzi Smyth, "Revision of Twenty-one Places in the Red Half of the Solar Spectrum, with a Rutherfurd Diffraction Grating at Madeira, during the Summer of 1881"; E. J. Stone, "Observations of Occultations of Stars by the Moon, and of Phenomena of Jupiter's Satellites, made at the Radcliffe Observatory, Oxford"; Mons. Loewy, "Réponse à la Communication fait à la Société Royale Astronomique par M. Marth au sujet de mon appareil pour la détermination des flexures."

THE METEOROLOGICAL SOCIETY.

DURING last year the Council of the Meteorological Society, having regard to the rapid progress, of late years, in statistical meteorology, and the uncertainty that still prevails regarding important questions relating to the physics of the atmosphere, considered it desirable that the Society should supplement the ordinary observations by a series of well-conducted experiments destined to throw light on such questions as the vertical decrement of temperature, the rate of ascension of vapour, the height of cloud-strata, the variation in the velocity of the wind at different elevations, &c. Steps have been taken during the past week to make observations on the first of the questions by the placing of thermometers at the summit and base of Boston Church-tower, which is 270ft. high. This tower is admirably situated for making such experiments, as it is isolated and free from any obstructions, and the ground is quite flat for miles round. By permission of the vicar, Canon Blenkin, the instruments have been placed as follows:—At the summit, one of Dr. Siemens' electrical thermometers (kindly placed at the Society's disposal by Messrs. Siemens, Bros., and Co.) and an ordinary thermometer are mounted in a small screen fixed to one of the pinnacles of the tower; on the roof of the belfry, which is 170ft. above the ground, a Stevenson screen has been mounted, containing maximum, minimum, dry, and wet-bulb thermometers. In the churchyard another Stevenson screen has been fixed, containing a similar set of thermometers, for comparison with those above. All the thermometers will be read every morning at 9 o'clock. The electrical thermometer consists of a coil of wire wound round a cylindrical piece of wood inclosed in a small brass tube; a third wire is joined to one of the wires, and the three, insulated by guttapercha, form a light cable, which is brought down to the base of the tower, and connected to a galvanometer, the terminals of which are in connection with the two poles of a six-cell Leclanché galvanic battery. The instrument is read by depressing a key, which causes the needle of the galvanometer to deflect, a pointer or vernier (moving a contact-roller upon a wire in a circular groove) is then pushed to the right or to the left upon a divided scale, until the needle remains stationary on the zero-point, when the electrical resistance of the wire is measured upon the scale. The number indicated by the vernier is then read off, and by referring to a table of equivalents the actual temperature in degrees of Fahrenheit is readily ascertained.

Simultaneous readings of the electrical thermometer at the summit of the tower, and of the dry-bulb thermometer in the churchyard, will be made frequently during the day by the verger of the church.

The World at the Advent of Man.—Prof. Boyd-Dawkins, continuing his lectures at Owens College, spoke last week of the pleistocene period of the tertiary epoch. Instancing the discoveries of animal remains, representing both extinct and living genera, he came to the conclusion that in the period with which he was dealing the area of the Mediterranean was much less extensive than is seen at present, its bed being well marked out by the present 400 fathom line. Taking that depth as representing the pleistocene shore, he found that the coast line of Europe included Sicily, Corsica, Sardinia, the Balearic Islands, and that land extended over the Straits, joining the two continents at Gibraltar and Malta and Sicily. On that assumption he could easily account for the presence in Europe of animals now exclusively African, such as the hippopotamus, the lion, and the great elephant, and also explain the discovery in Africa of fossil remnants of animals inhabiting colder and more northern climes. Another important point was the relation of Britain to the mainland of Europe. In that case, the 100 fathom line was the clue to the ancient geography, and that line, commencing on the coast of Norway, sank to the north of Denmark and then went out to the west, embracing the British Isles, and touching the present coast in Northern Spain. This union of these islands with the Continent explained the presence in the same fossil-bed of bones of the rhinoceros, the reindeer, the elephant, the great bear, and other animals originating in widely separated zones. A striking instance in connection with that ancient union of islands and continent was afforded by the habits of the Arctic lemming. That animal even now congregated once a year in Lapland in enormous numbers, and travelled in droves through the Scandinavian peninsula, finally marching into the sea. It was in this pleistocene age that the glacial period in English history occurred, and it was at this time also that we had the first traces of man's existence on the earth. Whether man lived before or after the glacial cold era he could not say, but the fact was indisputable that in the mid-pleistocene age men lived and hunted in England, using weapons which were probably of the most rough and savage type, but which were widely distributed over the earth, and formed the most rudimentary stage in the history of civilisation.

SCIENTIFIC NEWS.

◆◆◆

SIR CHARLES WYVILLE THOMSON died last week at the comparatively early age of 51. He will be best remembered as director of the *Challenger* Expedition, a post for which he was well fitted by his previous experience in the *Porcupine*. Owing to failing health the deceased professor resigned his chair in Edinburgh University last year, which he had held since 1869.

The Government "Endowment of Research" Fund of £4,000 is continued for the present year, but the special grant of £1,000 is withdrawn. Applications for grants must be sent into the Royal Society before the end of the present month.

Fifty-one candidates' names are "up" for election into the Royal Society. The council during next month will select fifteen, who will no doubt be elected in June.

Next Wednesday Professors Roscoe and Abel, as presidents respectively of the Chemical Society and the Institute of Chemistry, will hold a reception at the Crystal Palace.

Dr. W. R. Hodgkinson has been appointed Professor of Chemistry and Physics at Woolwich Military Academy, and Mr. L. C. Wooldridge has been elected Brown Professor of Pathology in the University of London.

The memorial stone of an observatory presented to the town of Paisley by Mr. Coats, of Ferguslie, was laid last week. The building adjoins the free library and museum, and a suitable equatorial with other instruments have been selected by Professor Grant, of Glasgow. The property will be intrusted to the Philosophical Institution of Paisley.

Dr. C. Siemens has recently contributed a remarkable paper to the Proceedings of the Royal Society. He holds that all the heat and energy sent from the sun find their way back to the great solar centre. The paper is much too long, and on too recondite a subject, for our columns.

No. 21 of the *Mineralogical Magazine* is a nicely executed geological map of Sutherland by Dr. Forster Heddle, to illustrate his paper on the Geognosy of Sutherlandshire. It is on a scale of half-inch to the mile, and indicates all the mineral localities.

The Glasgow popular science lectures were brought to a close last week by a lecture by Mr. A. R. Wallace on the biological relations of New Zealand and Australia, in which he pointed out that the differences between the two countries were of the most radical kind. The lecturer contended that deep-sea soundings gave trustworthy indications of prior land connections, and pointed out that where islands had natural productions almost exactly the same as those of an adjacent continent, the depth of water between did not exceed 100 fathoms.

The annual meeting of the Institution of Naval Architects will be held in the hall of the Society of Arts on the 29th, 30th, and 31st inst.

Apropos of the discussion about screw propellers, we note that drawings are being made in the United States for a steamship of 400ft. length by 60ft. beam, calculated to make the passage from New York to Liverpool in "five or six" days. The engines will be of 15,000 indicated horse-power. Nothing is said about depth, but no great improvement will be made until that is taken into consideration, and the engine-power above mentioned is, it will be noted, excessive—in fact the "hold" will be mainly "engines" and their accessories.

The Patents Bill of the Society of Arts is to be introduced by Sir J. Lubbock and Mr. W. H. Smith. It has been considerably amended, but still contains the clauses providing for a preliminary inspection of specifications, but not as to novelty or utility. The fees are reduced to £2 10s. on application, and £5 on the grant. Mr. Chamberlain will, it is understood, also introduce a Bill on the subject.

Herr Setterberg, in a communication to the *Annalen der Chimie*, says he has succeeded in isolating cæsium by the electrolysis of a fused mixture of the cyanides of cæsium and barium. The metal is silver-white, ignites spontaneously in air, and generally behaves like potassium.

A Berlin paper relates an amusing story of the famous German scientist, Alexander Von Humboldt, taking advantage of the exemption from duty of the covering of articles free of duty, formerly the rule in France. In 1805, he and Gay-Lussac were in Paris engaged in their experiments on the compression of air. They found themselves in need of a large number of glass tubes. This article was exceedingly dear in France at the time, and the rate of impost on imported glass tubes was something alarming. Humboldt sent an order to Germany for the needed articles, and gave directions that the manufacturer should seal up the tubes at both ends, and put a label on each tube with the words *Deutsche Luft* (German air). The air of Germany was an article on which there was no duty; the tubes were passed by the customs' officers without any demand, and arrived, free of duty, in the hands of the two experimenters.

The dressings of wounds sometimes acquire a blue or green colour. This was inquired into recently by M. Gessard, who found the cause to be a small mobile parasitic organism, which he was able to cultivate in neutralised urine, or a decoction of carrots. It is developed in saliva, sweat, albuminous liquids, &c. The blue colouring matter it secretes is the pyocyanide of M. Fordos. A current of sulphuretted hydrogen, or sodium-amalgam, makes it green, then yellow. The small organism has the same action, by reason of its avidity for oxygen. It may here be stated that M. Richard has lately given some interesting information (*Comptes Rendus*) about a special organism found in the blood of persons attacked by malaria. It is called the *Oscillaria malariæ*, is formed in the red corpuscles (which it renders viscous, so that they stick in the capillaries), and from these it issues in the form of a flexible rod or whip, which, under certain conditions, has a vibratory movement.

The remarkable experiments of M. Bjerknes, imitating electric and magnetic phenomena, by means of pulsating bodies in water, have excited great interest. Recently, M. Decharme has worked at such imitation by another method, using liquid currents, continuous, or interrupted, in air or in water. In one case a conical convergent nozzle, with thick rim, connected with the water-service, and held downwards with the hand, its mouth very near a smooth base, is thrown into vertical vibrations which may produce a sound.) A thin-rimmed nozzle acts still better; in this case, *repulsion* is first, in the other *attraction*. The sensation in the hand is quite like that of holding an electro-magnet, quickly made and unmade in succession. M. Decharme makes "hydro-electro-magnets" with two contrary poles, on the principle indicated, and, in various experiments (*Comptes Rendus*) obtains a *direct* analogy between hydrodynamic phenomena, and those of electro-magnetism and induction (in M. Bjerknes' phenomena, the analogy is *inverse*). Again, M. Elie describes, in the *Journal de Physique*, some ways of imitating the forces that act in a dielectric. Small equal spheres hung in water with wires are set in rotation through the wires at the rate of at least ten turns in a second. Two such spheres repel each other if the rotations are in the same direction, and attract each other in the contrary case. A solid flat surface brought towards a rotating sphere is repelled, and so on.

In different parts of Eastern Switzerland, on Jan. 31st, a meteor of rare size was observed in bright sunlight, between 2 and 3 p.m. According to accounts of persons at Uetliberg, near Zurich, Einsiedeln, and St. Gall, a noise was first heard; then one saw a snow-white lump floating in the air, apparently hardly 50 metres (166ft.) above the ground; a thin sulphur-yellow strip then branched off north-westwards, but presently contracted again into ball shape, the whole suddenly disappearing with play of red, white, and green colour. The meteor fell to the ground with strong detonation at Skauss in Canton Graubündten.

A noteworthy recent case of injury to a chimney from lightning has been recorded from near Douai. The chimney is that of the sugar-refining works of Sen-le-Noble, and is about 170ft. high. The photograph shows a great lateral gap about 30ft. long at the top; thence the course of the fluid downwards is traceable by an irregular fissure of various width. The lightning tore off the spout, deluged the furnace-men with soot, put out the gas-jets, and escaped to earth by a vent-hole.

With regard to connection of lightning conductors with the gas and water-pipe systêms of towns, a paper of directions has been recently drawn up by a Saxon Government Committee (*Deut. Ind. Zeit.*). The following are some of the points in it: Such a connection renders an earth plate superfluous, and is both reliable and recommendable. Those pipe-systems are suitable which consist of iron pipes with socket and nozzle joint and lead stuffing; flange combinations are sufficient only when they have strong screw-nuts. Should the conductor be near a flange-combination, it should be connected with the system on both sides of the flange. The conductor should be connected, where possible, by soldering with soft solder over as great a surface as possible. (Sundry directions are given for this, and for connection where soldering is not practicable). To give protection and facilitate inspection, the parts concerned in the connection should be surrounded with light brickwork. Connection should not be broken during a thunderstorm.

It is now known that tendons (or the terminal parts of muscles) contract; also that they have sensibility and nerves distributed to them. The contraction has been thought to be a phenomenon of reflex nature, that is, a return-action of the spinal cord, caused by direct excitation of the tendon-nerves. But M. Guerin finds reason, both in the structure and the action of tendons, to believe that their contractility is quite of the same order as muscular, and he holds that they show, like muscles, both voluntary and involuntary contraction.

A simple apparatus for getting rid of cockchafers and other nocturnal insects, has been devised by M. Vittellier, of Mantes, and is figured in *La Nature*. It depends on the attraction of light for these insects, and consists of a lamp placed at the top of a movable frame, and having four square-shaped narrowing cases, with metallic reflecting surfaces in the interior, placed round it. The insects fly into these, and strike against a pane of glass, at the bottom of which is a funnel-shaped aperture leading to a bag hung below; and into this they fall in great numbers.

Instead of the usual solid case of the Bell telephone, Herr Konigslieb, of Hamburg, provides a case in which the space between the membrane and the magnet is enlarged into a thin-sided sounding-case, and under this is a resonance-case, which surrounds the other at a certain interval. The resonance-case is perforated in several places. The author claims to obtain thus a considerable strengthening of the sound; also a purer and more distinct transmission.

The expansion by heat of sulphur, caoutchouc, hardened rubber, guttapercha, and paraffin, and the applicability of hardened rubber to compensation pendulums forms the subject of a recent interesting paper by Herr Russner in *Carl's Repertorium*. It is shown that caoutchouc has an expansion more than four times that of sulphur; hence, doubtless, the great expansion of hardened rubber depends essentially on the former and the amount of it present. Varieties of hardened rubber can be produced that have an expansion six to ten times that of iron, so the substance has been suggested for compensations —*e.g.*, a pendulum-bob might be attached to a hardened rubber tube capable of moving over the lower end of the pendulum-rod, and fixed below with a screw. By expansion of the tube the pendulum-bob would be raised. Herr Russner obtained satisfactory proof that the tenacity of the substance is sufficient for the purpose. Another point that had to be considered was the great increase in the expansion of hardened rubber with the temperature (very different from that of iron). The author recommends substitution of hardened cast steel for iron in the pendulum-rod, as this diminishes the divergence. The results with a clock having its pendulum compensated with hardened rubber proved to be quite favourable.

An interesting lecture on porcelain, its history, manufacture, and decoration, has been recently delivered at the Sorbonne by M. Lauth. It is reported in *La Nature*.

The Parisian Gas Company have recently organised at their works at Villette (which is one of their most important centres of production) a museum of the industry of coal-distillation. One finds in it samples of the principal kinds of coal employed, and specimens of all products obtained from the coal, from coke, heavy oils, and ammoniacal salts up to the remarkable aniline dyes, now so numerous. Further, the museum contains types of the principal systems of canalisation, distribution, regulation, &c., of gas. Among historic curiosities is the first gas-engine constructed by Lenoir. On the walls are various instructive statistical tables, in some of which the volumes of the products from a given quantity of coal are indicated very helpfully by means of a diagram.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

VARIABLE STARS.

[19809.]—In the table of magnitudes given by Professor Pickering in his courteous and valuable reply (letter 19072, p. 542, Vol. XXXIV.) to my inquiries, I observe that the estimate of ε Cassiopeiæ is considerably lower than might have been expected. In the case of the other stars, and in the case of the magnitudes given in Professor Pickering's letter in January's *Astronomical Register*, the estimates are larger—some, considerably larger—than those given by other observers (a circumstance due, I suppose, to a difference of standard). But though Professor Pickering makes the magnitudes of α Cephei, ψ Ursæ Majoris, α Persei, β Tauri, respectively, 0·4, 0·3, 0·17, 0·38, greater than those assigned to them by Sir J. Herschel; he makes the magnitude of ε Cassiopeiæ lower than that given for it by the author of the "Outlines." As it seems from this that the difference of light between ε Cassiopeiæ and other stars is greater now than in 1837, it would appear that this star is a variable of Professor Pickering's third class.

Professor Pickering's remarks at the close of his letter in the *Astronomical Register*, Mr. Espin's communication in your number for Dec. 30, and the above remarks, show very clearly the necessity, in photometric observations, for clearly defining the standards employed. In the letter from Messrs. Espin and Read referred to, there is one serious omission: it is said "our comparison stars were taken independently also," and as the results are, for the most part, strikingly accordant, it is unhesitatingly concluded that the method of observation is all that can be desired. But unless we know *which* stars were employed as standards of comparison, and what were the magnitudes assumed for them, we cannot properly compare the results of the comparison—we might almost as well seek to compare fractions of different denominators at a glance. To instance, take the following table:—

Star.	Espin.	Read.	Gemmill.
α Ursæ Min.	2·4	2·4	2·2
γ ,, ,,	3·5	3·0	2·8
δ ,, ,,	4·6	4·3	4·3
ε ,, ,,	4·45	4·4	4·2
η ,, ,,	5·3	5·1	4·5
γ Draconis	2·5	2·5	2·6
β ,,	3·2	3·0	3·1
κ ,,	3·8	4·0	3·8
θ ,,	4·0	4·0	4·05
λ ,,	4·3	4·2	3·9

My results agree pretty closely with those of Messrs. Espin and Read; and when increased by 0·2 (the difference between their estimate of Polaris and mine), the differences are, for the most part, almost entirely removed. But the causes of these differences cannot be ascertained, unless the principle upon which the magnitude of some one among these stars was fixed is known. As my estimate of Polaris is based on the assumption that α Persei is of magnitude 2·1, and as α Persei was my comparison-star, it follows that the reasons why *my* estimates differ from *theirs* could not be examined into unless I knew their estimates for α Persei, or they had stated their comparison-stars, so that I might have placed my estimates alongside theirs. All star-magnitudes are comparisons: as such, various series cannot be compared *inter se* unless the scales upon which they are founded are known.

To follow out my own principle, and give data upon which my results can be understood, I will state my own scale. I base any one series of observations on the assumption that the magnitude of a certain star is a certain amount found by previous sequencing based on the assumption that Capella and Vega are normal first magnitude stars and similar in brightness. I afterwards investigate the magnitude of that star by numerous and careful sequences. Where I have no cause to suspect variability, I take the mean of the various results; but I am slow in so doing, as it is not very easy to tell whether the apparent differences in the magnitudes found at various times for any one star are real differences in brightness, or accidental differences due to weather or condition of eye—by always assuming them to be accidental, we should, no doubt, lose valuable indications of slight or temporary variability. In this way I hope to determine the constancy of light of the stars employed as standards. If I find the earlier assumption wrong, I apply the correction in reducing the result. As it is, I have found α Persei constant at 2·1. Sir J. Herschel gave it as 2·07. I have a suspicion, however, that its *colour* alters. By examining the differences between the extremes of sequences headed by Vega and Capella, I hope to ascertain if any changes *do* take place in these stars. Sir J. Herschel was of opinion that he had found Capella become brighter than Vega between 1837 and 1846.

A careful examination of η Ursæ Maj. has revealed indications of the five-day period spoken of by Mr. Espin, in his letter in your number for Nov. 25.

Colour of Dubhe.—Jan. 2, singularly red; Jan. 8, red, but deeper tint; Feb. 14, red colour very decided.

In letter 19514, p. 352, there were a few misprints; the principal being "sensitive-toned" for "sensitive to red."

S. Maitland Baird Gemmill.

Glasgow, March 10.

JUPITER.

[19810.]—I obtained a daylight observation of the red spot on March 3rd, 1882, as follows:—

	H.	M.
Preceding end on C.M.	1	24
Middle on C.M.	1	51
Following end on C.M.	2	21

When central the spot was fairly well defined, though, of course, with nothing like the distinctness of its evening apparitions.

The brilliant equatorial spot has been closely watched here, whenever circumstances permitted, up to the present time. On Feb. 26th and March 3rd it was recorded as very bright and large when crossing the C.M. of Jupiter. The conjunctions of this object with the great red spot, which recur at intervals of about 44½ days, are extremely interesting to witness, and I shall be glad if any of your readers will endeavour to observe the next, on the evening of March 23rd, when the two spots will have nearly coincident longitude, as they transit the C.M. at about 8h. 26m. p.m. On March 21st at 6h. 47m. p.m. the red spot will be about at mid-transit, while the white spot will be placed N. of its following end, and will arrive at the C.M. some 27 minutes later than the middle of the red. It is important that the relative positions of the two objects be carefully determined by observation on one or both of the evenings mentioned. The actual time of conjunction can then be readily computed as the greater velocity of the white spot enables it to gain 13m. 24s. daily (= 8·1° Jovian longitude) on the red spot. Moreover, the ensuing conjunction on March 23rd is the last which can be observed until the planet's reappearance in the morning sky, when, should the same markings continue visible, they will again occupy nearly the same longitude on the planet on August 3rd. But there are certain irregularities of motion which may affect the relative positions of the spots in the interval, so that the predicted date may not be found exactly conformable with that observed, though both the spots appear to be of marked permanency, and to display a great difference of mean velocity, which has been maintained for two years with little deviation.

Bristol, March 11th. **W. F. Denning.**

ADJUSTMENT OF MIRRORS.

[19811.]—The difficulties suggested by your correspondent, Wm. A. Haren (19805) appear to me purely imaginary: there is no optical necessity for an absolutely exact adjustment of the axis of the tube to the axis of the mirror. The flat is supported in the tube by three bars and a bearing-block, the hole in which should be, and is usually, fixed centrally in the tube by simple measurement. Nothing more is required; the usual adjustments alone then prevent any "tilting" of the mirror. The tube may even be of any shape or size if large enough not to intercept the cylinder of light surrounding the axis of the mirror, and a "stop" could be used to exclude extraneous rays.

Southampton. **T. A. Skelton.**

[19812.]—In reply to Mr. Haren's letter, 19808, p. 11, I some time since called attention, in the English Mechanic, to the difference between mechanical and optical adjustments, the latter being necessary, to be definite, to the perfect performance of telescopes, the former not; and I alluded to the position of the flat as regards the axis of the large tube, as one of mechanical adjustment only. The best and proper place for it is in the axis, as nearly as ordinary measurement and the truth of the tube to a cylinder will allow, that is mechanically; but optically it is of no importance at all. Mr. Haren will, I think, see this to be the case for the following reasons:—

The mirror is constructed to receive a cylinder of rays from the object observed, which are all parallel to its axis, and its parabolic form converges these into a cone with its apex at the focus. The flat intercepts this before it comes to a focus, and reflects it in the direction required, most conveniently at a right angle, or nearly so, but, theoretically, at any angle. What is necessary is, therefore, that the mirror should be perfectly square, both longitudinally and transversely, with the line joining the centre of the mirror and flat, and this is the case where the spot in the centre of the mirror is seen central in the reflection of the flat.

The flat has then only to pass this spot through the axis of the eyepiece, which is done when the reflection of flat is central in the pinholes.

Nothing is here said about the large tube, and indeed it is nothing but a mechanical or conventional arrangement, to enable the two mirrors to be used conveniently with the eyepiece, and to keep off divergent rays.

It is well known that an 8in. mirror, for instance, will perform better in a tube intended for a 12in. than in its own, for reasons which do not now concern us, and if this is so, it is evident that it cannot be of any consequence, within reasonable limits, where the sides of the tube are, and what is their relative position to the axis of the mirror.

All that is necessary is that the tube shall not intercept the cylinder of rays as it falls on the mirror.

Fordingbridge. **T. Westlake.**

MEDICAL REPLIES.

[19813.]—Paralysis (46295).—The subject of paralysis is too large and too complex to enter upon in the vague way in which "C. R. B." wishes. But I may point out that there are various main causes for paralysis. 1st. Disease of the central grey nervous masses, situated within the cranium or spinal canal. 2nd. Disease of various fibrous nerve tracts which connect and co-ordinate the various grey centres (known as commissural fibres). 3rd. Disease of the fibrous nerve tracts (commonly known as nerves), which run out from the central bony cavities, and convey the nervous impulses to the muscular masses in the limbs, which are the true motor organs. 4th. Disease of the muscular masses themselves, as in some cases of chronic muscular rheumatism, lead poisoning, &c. Now, to say which of these is the real cause of the paralysis, and how far certain other factors enter into the condition of a particular patient, is one of those problems which nothing but the skilled eye and the skilled cross-examination of a practical physician can solve. It is, in fact, that prime factor, *diagnosis*, which, alike in the workshop and at the bedside, is the result only of a scientific grip of the subject, practical training of the senses, and inherent artistic capacity for the work. An amateur mechanic may write admirably and usefully upon a subject—say, the lathe; he may have a perfect scientific grip of the subject and inherent artistic capacity for mechanics; but if he have not that practical training of the senses, and that knowledge of materials which is only to be mastered by patient labour in the workshop under skilled teaching, he will select, say, an unsuitable piece of steel for his mandrel; and after producing a beautiful model lathe, with splendidly-constructed chucks, his mandrel-neck will abrade, or his mandrel-nose bend or break, and all his work is useless. Now, in mechanics, the amateur makes a "waster," but he can begin again, and, after a certain number of experiments, such an amateur will master his subject. But if a patient is treated upon a wrong diagnosis, not only is the one opportunity for restoration lost, the patient's system is injured by misapplied drugs, or other treatment which only aggravates the original disease, and adds to his sufferings. Now, if "C. R. B." had a valuable chronometer out of order, he probably would pick out some skilled chronometer maker, and learn from him exactly what was the matter, and what was needed to set it right. He would never attempt to get such information by letter writing. Many years ago, I carried a watch made by Barraud and Lund, which went excellently until a strange man had cleaned it; after that the watch stopped suddenly in the most mysterious way, and at all sorts of odd times. Repeated tinkering with the watch left this capricious and annoying defect uncured. Then the watchmaker discovered that the balance-wheel was too heavy or too light, I forget which, and he put in a new balance-wheel, and kept the watch a month, during which time it went perfectly. On getting it back, the watch stopped again just as before. Ultimately, I took to studying this extraordinary watch for myself, and I found out that so long as it was hung upon a nail it went perfectly, but that when laid upon its back if often stopped. Upon discussing this with another watchmaker, he predicted that one of the pins which held the movement up to the dial-plate was too loose, and that when the watch lay upon its back the movement sometimes dropped, and the hands, clinging to the dial-plate, stopped the watch. On testing the watch, this proved to be the case, and on simply correcting the pin, my poor watch went as well as could be expected after Barraud's balance had been tinkered away. This fairly illustrates what I mean by *diagnosis*, or a clear statement of what is and where lies the cause of the disease. Now, many a man's inside is tinkered away by drugging and other treatment given on an utterly wrong diagnosis, and "C. R. B." tells us that "he has been under the treatment of several medical men, and tried every known remedy to regain his locomotive powers," yet he never seems to have learnt what is the cause of the paralysis or where that cause is located. "R. C. B." had better consult the best physician in his locality, so as to ascertain these fundamental points and learn the precise name which should be assigned to his paralysis. Speaking generally, I should say that a patient who has "tried every known remedy to regain his locomotive powers" before having ascertained these primary facts must have suffered much at the hands of his doctors, and is not now a very promising case. But if he will ascertain these data I may be able to advise upon the machine which he is projecting.

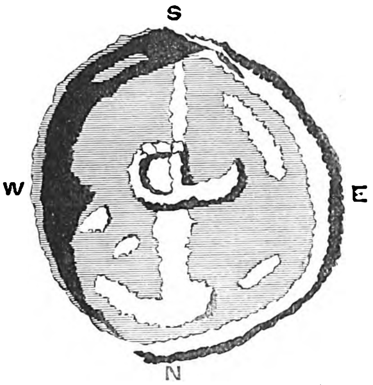
The Teeth (46361). Black specks on the teeth are sometimes due to congenital pittings upon the enamel, these little pits filling with dirt. Such pittings are incurable, and all that can be done is to wash the teeth carefully with tepid water night and morning, and use a little chalk upon a tooth-brush or the end of the finger so as to thoroughly cleans the pits. Such pits may sometimes be safely lessened by smoothing down the surface of the enamel and rubbing off the sharp edges of the pits by means of a little fine emery upon a small ivory burnisher. This makes them less conspicuous, and also makes them shallower and less prone to get discoloured. Other black specks there are which come upon sound teeth where their sides abut upon a cavity in a decayed tooth. Here one tooth becomes hollow; its cavity retains particles of food which turn sour and act upon the enamel of the sound tooth which stands at the side of the cavity. Thus decay in the teeth is infectious, and such hollow teeth should always be extracted so as to save the contiguous teeth, or should be carefully excavated and stopped with gold. To preserve the teeth, avoid all quack preparations, rinse the mouth carefully with warm water night and morning, using a tooth-brush and a little elutriated chalk to cleanse them, if necessary. (2) Avoid such cooks as do not wash grit carefully out of currants, salads, &c., for careless chewing of food containing shot, particles of stone, fragments of chopped bone, &c., often splits the enamel of the teeth, and ruins them. Seizing needles by the teeth, cracking nuts, &c., are also fertile causes of destruction. (3) Never take acid medicines, acid solution of steel, and other drugs, which certainly ruin the teeth and rarely do good otherwise. In such rare cases as may be necessary, these corrosive medicines should be sucked through a straw or glass tube, and swallowed without coming into contact with the teeth; the mouth also should be instantly rinsed with clean warm water. (4) Mothers who would preserve their own teeth from softening due to absorption of their earthy matters, and who would lay the foundation for strong teeth and solid bones in their children should take foods which contain abundance of earthy matters, such as oatmeal-porridge and milk, while nursing and before the birth of their children. (5) Persons having decayed teeth should cleanse the cavities out carefully after meals with a quill toothpick, and rinse their mouths after each meal. A piece of silk thread held between the fingers and passed backwards and forwards between the teeth is a safe and excellent means of cleaning out the interstices. The importance of preserving the teeth while young is much greater than is generally realised until the teeth are ruined.

James Edmunds M.D., &c.

Grafton-street, Bond-street.

PLINIUS.

[19814.]—The unfavourable weather of the last few weeks has prevented me from obtaining more than two observations of this object since the date of my sketch (English Mechanic, Feb. 3, p. 517). On Jan. 27th, 5h. 30m. to 6h. 30m. M.A. 8d. 1h., I made the subjoined drawing of the formation



which shows the general character of the two nearly central objects on the floor observed by M. Gaudibert and myself on Jan. 25th. The most W. had the shape of the letter D reversed, and on its S. side were two bright peaks. The E. object seemed to consist of a hook-shaped ridge (or mountain) extending E. from the N. side of its neighbour. On 24th Feb., 7h. to 7h. 30m., I had a very favourable view of Plinius, and all the features observed on Jan. 25th were again seen with the addition of a small but very distinct craterlet about half-way between the crateriform objects near the centre and the S. wall. It was nearly in a line with the two minute craterlets on the N.W. side of the floor and on the ridge (or range of low hills) which extends from near the centre to the S. wall. In the *Intellectual Observer*, Vol. VIII., p. 29, Mr. Webb, referring to what he terms "the luminous central hill" of Plinius, says—"on two occasions, with two different instruments, and with an interval of more than twenty-five years, I have seen the two summits of the central hill figured by B. and M. as minute craters. Such illusions may easily take place when the shadows of small eminences fall among other elevations of a similar character, and show the necessity of caution in forming conclusions under these circumstances." I have no doubt that the two large crater-like objects seen by M. Gaudibert and myself on Jan. 25th correspond to the "minute craters" mentioned by Mr. Webb, though it is difficult to understand, even after making due allowance for differences in the magnifying power employed, how objects which, under suitable angles of illumination, are now so prominent, were once described as minute. I am much obliged to Mr. Herbert Sadler (letter 19760) for his copy of Plinius from Schmidt's map. The latter shows two openings in the N. walls of both craters. On Jan. 25th and Feb. 24th, there was a very evident break in both the N. and S. walls of the W. crater. Powers used 284 and 350 on an 8½in. Calver reflector.

Bedford, March 4th. **Thos. Gwyn Elger.**

HOW TO MAKE A CHEAP AND ORNAMENTAL BOOKCASE.

[19815.]—In response to the appeal made in letter 19777, I send sketch of a cheap, serviceable, and ornamental bookcase for a small room, suitable to fix up on wall-spaces between two doors or windows.

The shelves hanging on strings, which, doubtless, the wife of many a mechanic has found out, with a little extra weight, or by the act of pulling out a book the whole lot comes down, is one of the worst forms and plans for holding books together. The large and least-used books are at bottom, and the small books nearly out of reach at top; the whole exposed to dust, and, if hung low as a sideboard level, the large books project in the way too much to make the sideboard useful.

I have made several bookcases, and given to those needing such, but the simplest and most serviceable is shown by Fig. 1, side elevation. I have mostly cut the sides out of ¾in. or ⅞in. mahogany, or any hard, close-grain wood, generally odd pieces, from 3ft. to 4ft. long, 12in. wide, for top end, and 2in. at the bottom end, with fine scrolls. The large overhanging at top gives a protection to all from dust, by having a light ⅜in. thick top put on it. The first shelf, at A, shown by dotted line, will take books 13in. deep, 11in. wide; the next, B, 11in. deep, 7in. wide; the next, C, 9in. deep, 5in. wide; and D, 7in. deep, 3in. wide, or thereabouts, the whole resting on a sideboard, S, with strong wall-staples near the top. From 2ft. to 3ft. wide, from side to side, will make a bookcase to hold from one to two hundred books.

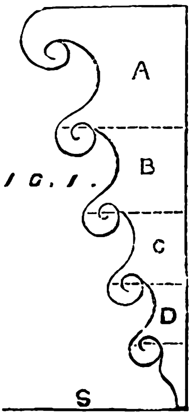


FIG. 1.

The shelves are of ¾in. deal, with the front edges faced with a strip of the same sort of wood as the sides. These shelves are recessed into the sides ⅛ of an inch, and glued and nailed if necessary. A light thin backing of wood or stout paper completes the job, except staining the deal to match the hard-wood.

If all of deal, it may be sized and varnished; but for a cheerful and elegant-looking stain, the deal, or, better, red pine, without knots, can be washed over with ordinary red ink and size. It resembles no wood in common use, but a pink-coloured wood, now and then seen in inlaid work. A coat of varnish should follow.

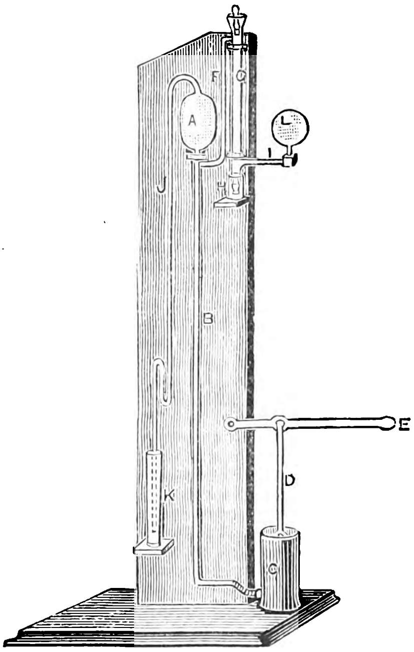
P.S.—If a curtain front is put to cover up the books, let it be on a roller the same as a window-blind, fixed at top.

J. Charles King.

SUTTON'S APPARATUS FOR THE RAPID PRODUCTION OF HIGH VACUA.

[19816.]—I have just received my English Mechanic for Nov. 11, 1881, in which, under the heading "Obtaining and Measuring High Vacua," there is a description of Prof. Rood's improved Sprengel pump: *its limit* is stated to be arrived at "when the leakage of the apparatus is equal to the amount of air that can be removed in a given time."

I send you a description and sketch of a vacuum pump invented by myself some time ago, and which, you will see by its construction, *has a higher limit still*, as the amount of air that can be removed in a given time *exceeds the leakage* many hundredfold; in short, the air can be withdrawn more rapidly than it can leak in. Its construction is simple; there are no stop-cocks nor valves; it is not liable to derangement, and will do in a few minutes that which takes hours on the Sprengel principle.



It is the result of studying the defects of the Sprengel pump.

It occurred to me that the mercury in a Sprengel pump, having to go through the form of numberless drops, the entire surface of the mercury is exposed to the influence of the high tension of the vacuum, and, therefore, air that would with mercury in the mass be retained cohesively, would, in the Sprengel principle, be given up to the vacuum. Another fault I considered to be, that mercurial vapour must be formed at these high tensions, given off from the drops—a fact that can be verified by examining microscopically the junction of a Sprengel fall tube, with its connecting tube to receiver; a gentleman of high scientific eminence having told me that in conjunction with a well-known English scientific gentleman, they had observed this defect.

To overcome these objections I argued that:—

(1) The air must be removed rapidly.

(2) That the mercury must not be in the form of drops.

(4) That the mercury must not leave the pump, but must be used continuously.

I have succeeded in accomplishing this, as the following will show.

A is a glass globe; at its lower end is attached a glass tube B, 36in. long; the lower end of this tube is bent to a right angle, and attached by a short piece of rubber tube to a cylinder C; in this cylinder a piston D is worked by the lever-handle E.

From the upper end of tube B, a branch tube F rises, and is bent to a right angle at the top, and joins the desiccating-tube G, which has its upper end widened into a funnel, and an indiarubber stopper fitted in so as to leave the funnel surrounding it. The lower end of G, also has a rubber stopper, which is surrounded by a glass cap H.

About 2in. from lower end of G, a tube of glass, I, projects, to which is attached the vessel to be exhausted, L.

From the upper portion of globe, A, a glass tube, J, of fine bore, rises, and bends down parallel to B. About half-way down tube J bends back on itself, then returns on its downward course and enters the tall conical vessel K, reaching to near the bottom.

To set the pump in action, the short rubber tube is removed from B and C, and a current of hot air passed for some time through tube B, and thence through the whole of the pump, driving out all moisture and leaving the pump warm and dry.

The rubber tube is then connected and sealed between B and C, and pure mercury previously dried, placed in cylinder C, by removing the piston, which is done by taking a pin out of the junction of D with E, the piston being returned to its place.

The rubber stopper is placed tightly in lower end of desiccating tube G, and its cap H filled with mercury, making an hermetically-sealed joint. Pumice soaked in sulphuric acid, or phosphoric anhydride, is then dropped into G from its upper end till half full; the upper half then being filled with gilded pumice, the rubber stopper belonging to upper end of G is now tightly pressed in, and the funnel end filled with mercury, thus hermetically sealing this joint.

The apparatus is now ready, and is worked by pressing the lever E, and thereby forcing the mercury up into tube B, thence into globe A, the mercury also rising in branch tube F, isolates the vessel L and its connections from communication with globe A.

The mercury being still forced into A forces the air out by the fine tube J, and when the mercury begins to rise in K, the lever E is raised, and the mercury falling back from A, produces in top of A a Torricellian vacuum. The mercury in K now rises into J, until the column of mercury in J exactly balances the atmospheric pressure at K. Any air that may rise in the bottom of J cannot pass the bend, owing to the specific gravity of the air being less than the mercury.

The lever E still being raised allows the mercury to fall from A, and also from the branch-pipe F, until, having fallen below the junction of B with F, communication is restored, and the air expands over from L, and its connections, into the vacuum in A, the mercury column in J lowering at the same time.

The lever E is now pressed down again and the same action takes place as in first stroke, a mass of air equivalent to the capacity of A being removed at each stroke of the piston.

The rapidity with which the vacuum is produced is proportional to the ratio of the capacity of A with the capacity of vessel to be exhausted and connections.

And as the globe A can be made very large, and thereby a great bulk of air removed with each stroke, it follows that the limit of the pump is very high, much higher than it can possibly be with any form of Sprengel.

The gilded pumice is to absorb any trace of mercurial vapour, and the chemical substance in tube G to absorb moisture.

In this pump there is little chance of mercurial vapour forming, as the mercury is not divided into a number of small drops and under high tension for a long period of time.

It will be seen that my form is a departure from the usual mercury pumps, as the mercury is worked in the mass and without the aid of stop-cocks or valves. It does its work perfectly and rapidly.

I have not yet measured the vacuum produced, as I cannot obtain the appliances here; but it is easily seen that the vacuum must be very high, and possibly reaches the theoretical limit. In conclusion, the pump is not patented, and therefore all have the liberty of using it.

Henry Sutton.

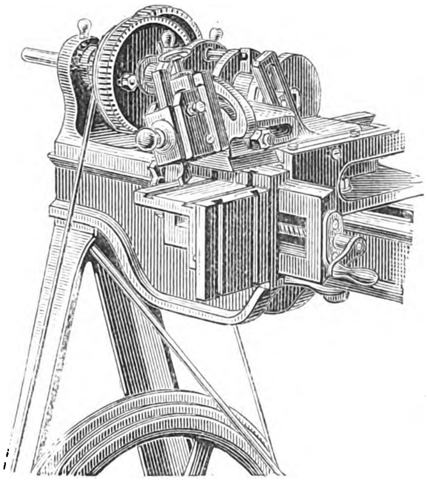
Australia, Dec. 28, 1881.

SHAPING ATTACHMENT—TO F. CARRE.

[19817.]—HEREWITH I inclose description (which is borrowed from Northcote), and perspective view of Booth's shaping machine. I trust the engraver won't be puzzled.



The instrument, when bolted to lathe-bed, is ready for work. It is capable of shaping a surface 7in. long and 3in. wide at one setting. The motive power is obtained from lathe-spindle, the driving-pin of which engages into a space cut in the machine driving-plate. At the other end of the same spindle as the driving-plate there is a crank-plate, with adjustable crank-pin; but this pin, instead of being connected direct to the slide, is arranged to slide up and down a slotted arm, a square slide block being, however, interposed between the crank-pin and slot to increase the wearing surface. The slotted arm is fixed below upon a stud attached to main casting of machine, and the motion of the crank-pin up and down in the slot causes the arm to oscillate around this stud or fulcrum, but its motion has a varying angular velocity, which becomes greater as the crank-pin arrives at that end of the slot nearest the fulcrum, and less as it approaches the other. In this apparatus the tool moves backwards and forwards over the work, to give the cutting stroke, whilst the work only moves sideways to give the traverse between the cuts. The slide carrying the shaping-head and slide works in V's formed in main casting. It receives its stroke from the slotted arm by a strong connecting-rod jointed to the middle of the slot, and at its other end to the slide by a pin, which is susceptible of a horizontal adjustment. As the slot-arm oscillates it gives a reciprocating motion to the shaping-slide; but owing to the varying angular velocity of former, the slide moves forward slowly and returns faster. Automatic motion is given to the work by means of the ratchet and click (seen on the left of the machine) upon the traverse-screw, actuated by a cam-groove cut in the reverse side of the crank-plate.

Has "O. J. L." come across the overhead apparatus just brought out by this same firm?

C. H. D.

LATHES AND LATHE-MAKING.

[19818.]—THE reply (19770) of Mr. Evans must have been read with great satisfaction by very many besides myself; and in taking advantage of his kind invitation to be more explicit, I would say, that I think it would add to the value of his papers if he gave some such data as he would place in the hands of a workman, who could construct a machine when he knew its general dimensions. Our esteemed instructor is doubtless well aware, that nothing is more unsightly or inconvenient than, say, a slide-rest for a 5in. centre, made strong enough, and, in some respects, big enough, for a heavy 7in. machinist's lathe. Every pound of surplus metal, like every pound of superfluous flesh, is a useless incumbrance.

For my own part, I should not like to see the general plan of Mr. Evans's papers interfered with. He has succeeded in making a dry subject interesting, but to load his remarks with numerical details would make it wearisome; a short table, which might be printed in lesser type and annexed to each mechanical section, would supply all that is needed. Anyone could then copy this into a note-book, and thus have a satisfactory guide to work by.

For instance, turn to page 221, on the Dome Chuck. A table might include: Length and thickness of boss; length, breadth, and thickness of slide-plate; thickness and height of centre of the standard. Next, on page 437, the slide-rest. Length, breadth, and thickness of foundation-plate; height of socket-boss, height and diameter of screwed part and pitch of screw. Length and breadth of face of main slide, vertical thickness of bars, and size of nut-channel. I need not go on to the other parts, as Mr. Evans will see what is needed from the preceding outlines. Such particulars, printed in the ordinary form, *e.g.* ($8 \times 3 \times \frac{3}{4}$), would occupy little space and be convenient for reference.

In connection with this subject, may I offer a suggestion to our friend "Cast Iron"? If he would give a few letters on making the patterns for the following articles, they would be very useful—viz., heads, beds, rests, and other adjuncts to the lathe, followed by others relating to the steam-engine. Mr. Rose's articles, though excellent for general engineering, do not include particulars of such appliances. Cannot small parts of mechanism be cast of iron similar to that of which "Blakey's Boot Protectors" are made? This appears to be a soft zinc-coloured iron, easy to work, free from hard spots, and may be bent without snapping. Are they made of malleable cast-iron?

"Aldebaran," in his practical instructions for fitting up a 2in. telescope, very sensibly recommends amateurs to avoid the use of screws as much as possible. If the cells are made a little deeper, I think they will hold nearly as well for practical purposes as screws—that is, for eyepieces and for o.g.'s, a few very small screws might be inserted, if there was any danger of the cell being shifted. Some time back "Sunlight" promised a sketch of a simple optical screwing apparatus, but the promise was all that appeared.

Many would doubtless be surprised to learn that a good 2in. o.g. could be bought for 7s. or 8s. I do not think there is any necessity to withhold the name or names of those opticians who sell such o.g.'s unless they so desired. They being only the dealers in, and not the makers of, such lenses, no injury could be done to anyone, by mentioning where a 2in. French lens could be obtained at that price.

Orderic Vital.

[19819.]—I HAVE to thank Mr. Evans for his courteous reply to what must have seemed to him rather a fault-finding letter, and it will go far to clear up my difficulty: the other points will probably evolve themselves in working. Referring to one of Dr. Edmunds' remarks as to the depth of screw-threads (or the difference in diameter at top and bottom of thread) it is easily calculable for any given angle, for if p be the pitch of the screw, and d the depth of the cut in making it, we have $\frac{1}{2}p/d$ = tan. $\theta/2$ where θ = angle of screw-tool. $\therefore 2d/p$ = cot. $\theta/2$. $d = \frac{1}{2}p$ cot. $\theta/2$, or if t = thread = $1/p$, d = cot. $\frac{1}{2}\theta/2t$ and the difference in diameter is twice this. in the case of $\theta = 60°$ cot. $30° = \sqrt{3}$. $\therefore d = \sqrt{3}/2t = \cdot 839/t$.

I should very much like to know how, in the earliest period of mechanical engineering, screws were first produced; indeed, now the subject (happily) has once more come to the fore in "ours," if any correspondent could give us a sketch of the history of the lathe, and the development of some of its parts, it would be of great interest to a large section of our readers, I imagine.

Scorpio.

ORNAMENTAL TURNING.

[19820.]—IN reply to the letter of "A Country Parson" (19806), I take the opportunity of pointing out that the class of turning represented is of quite a different description to that done by Mr. Coulson, whose production is very fine; and, moreover, to work up the lower parts to anything like the proportions of a cocoa-nut naturally grown, is not an easy matter. I think if our friend could, or would, see the original, his adverse opinion might be changed; and although it may not meet his taste, I find it appreciated by many of our correspondents who do this class of work.

J. H. Evans.

DYNAMO-MACHINES.

[19821.]—IN reply to "Quæstor's" inquiry, dynamo-machines may have their field-magnets excited in four different ways. In the first, the "main" current is used for exciting the magnets: in this case, one armature brush is connected to one end of wire on field-magnets, the other end of wire being taken to the lamp (or lamps, as the case may be). In the second method, the "shunt" current is used, the armature being arranged so as to give rather more current than is needed for external work, a bye-pass, or shunt wire, is wound round the field-magnets so as to take a portion of the current. The wires leading to the lamps are connected to the armature brushes, as are also the two ends of the wire wound round field-magnets.

In the third method, adopted, I believe, in the Brush machines, the advantages of the two preceding methods are supposed to be combined by the combination of the methods, and if properly proportioned, it should give good results. The arrangement of wires is evident.

In the fourth method, a "separate exciting machine" is used, and the wire on the field-magnets of the large dynamo must be fine or coarse, according to the kind of exciter used. The lamps are connected to brushes, and field-magnet wire to terminals of exciter, which, of course, will also excite itself. The theoretical weight of wire required in any given machine to give an equal current of the same electromotive force with the same expenditure of energy (or horse power) will be the same in each method, and the plan adopted must depend on the work. If the resistance is constant, it is not a matter of importance which system is used; if the current is required to keep up in quantity in spite of an increased resistance, "the shunt" should be used; but where a machine supplies a single arc-light I much prefer the main, as a slight increase in the resistance of the arc diminishes the current, and this, reacting on the field-magnets, still further reduces it, so that the lamp quickly adjusts itself and brings the carbons to their proper position; but if the shunt is used, an increase of the R of the arc throws so much more current through the field-magnets that the main current may be actually increased, the adjustment of the lamp then taking place in the wrong direction, an abnormally long arc is produced, which gives a fine chromatic effect, but is not suitable for practical lighting. Dr. Siemens, in his paper on his shunt-current machine, states that the R. of the field-magnets should be made at least ten times that of the armature, and that the extra R. should be made up by adding to the length, and not by reducing the size of the wire. This gives the shunt machine an undue advantage; and he states that the principle of the shunt-current gives a better result as regards horse-power, the fact being, that if an equal weight of wire be used, the two methods will give, practically, the same result. It is easy to show that if the weight of wire is the same, the power absorbed to produce a given current under an equal electromotive force, or what is the same thing, through an equal resistance, will be also equal. To take definite figures. A 10 ampére current is required through 4 ohms, which will require an E.M.F. of 40 volts. I have previously given approximate weights of wire for this size of machine.

Suppose that 4,000 feet of wire are wound on the field-magnets, and that it is of such a size as to give a resistance of 10 ohms (this would be about No. 16 B.W.G., and 50lb. of it), then using this wire as a shunt, as the E.M.F. is 40 volts, the current passing through it will be 4 ampéres, and the current evolved by the armature will require to be 14 ampéres. Suppose the R. of the armature to be 1 ohm, then the external circuit 10 ampéres, with 40 volts E.M.F. = 400 ampére volts; the field-magnets 4 ampéres, with 40 volts E.M.F. = 160 ampére volts; the armature 14 ampéres (it will require 14 volts to make 14 ampéres pass through 1 ohm), 14 × 14 = 196 ampére volts. Total number of ampére volts, 756.

Now suppose the same machine (that is, a machine of the same pattern) is made to work on the main-current principle, and it will be seen that the ampére volts required to give an equal external current will be the same if the same weight of wire is used. As there were 4 ampéres passing through 4,000ft. of wire, and it is necessary to magnetise them to the same extent, and there will be 10 ampéres (or the main current) now passing, the wire will only require to be 4-10ths of its previous length, or 1,600ft., and as it has to be the same weight (50lb.), its resistance will be found to be 1·6 ohm. The armature wire having only 10 ampères passing instead of 14, will only require to be 10-14ths of its previous size, which for an equal length would give it a R. of 1·4 ohm.; but as it is proposed to use an equal weight, it will be necessary to make it four-tenths longer, which makes the R. up to 1·96 ohm.

Then the current everywhere being 10 ampères, we may add all R.'s together: External R. is

4 ohms., magnets 1·6, armature 1·96; total, 7·56 to force 10 ampères through, which will require E.M.F. of 75·6 volts; therefore total energy is equal to 756 ampère volts as before, thus proving that the economic efficiency of the two systems is the same, provided the same amount of capital is invested in copper wire.

This naturally leads to the question (asked by J. Hezmalhalch, query 46233) as to the best size of copper wire to use in a machine. This simply depends, as has been pointed out by Sir W. Thomson, with regard to leading wires (and the same calculation may be applied to the machine) on the interest on the cost of copper as compared with the cost of power, for the larger the wire the less the R, and therefore the less will be the work uselessly absorbed in heating the wire. But in the machines that are likely to be made by amateurs the cost of power will be of less consideration than the first outlay, and the only limit it will be practically necessary to consider will be the fact that a certain size must be used to prevent such undue heating of the wire as would be likely to injure the insulation. This is the basis on which I gave No. 12 as a suitable size for conveying about a 10 ampére current.

"J. H." also asks why in finding the horse-power I multiply by 44. He will find the same figure used this week (March 10) by Prof. Ayrton. It is the value in foot pounds of a current of one ampère under an electromotive force of one volt acting for one minute. A useful figure to remember (derived from this) is that 750 ampère volts are equal to one horse-power, 44 / 33,000 = 750. My letter is much too long already, so that I will not remark on "Conrad's" letter till next week.

R. P.

[19822.]—THE gentlemen who are so anxious to have full details of dynamo-machines can scarcely be aware of the calculations required to determine the best form of machine to give a particular result. Many machines can be made on the same principle to give similar results; but to determine the best size, and quantity of wire on field-magnets and armature-coils, is a matter involving much experiment and labour. It is not likely that those whose business it is to work out these things will gratuitously present their results to the world. I have neither time nor inclination to do so; but if any gentleman possessed of the requisite skill and appliances likes to make dynamo-machines, my advice to him is to first study thoroughly the laws of magneto-electric induction, after which he will be in a much better position to produce a satisfactory result than if he had merely put the machine together from rule-of-thumb instructions. I may give one hint to some disappointed ones—viz., that a dynamo-machine—self-exciting—connected up in a particular way, can only give a current when revolved in one direction. Hence, if the disappointed amateur, who can get no current from a seemingly perfect machine, will reverse his field-magnet connections, he may be gratified with a good result. I have never seen this fact in print. It is correct enough, as a little thinking will show anyone conversant with the subject.

"Conrad" (letter 19799) criticises adversely the Brush machine. Now, I don't want to be rude; but the context suggests the doubt to my mind that "Conrad" does not know the Brush machine connections or arrangement of field. He is under the impression that the bobbins are only able to contribute to the current during a quarter of each revolution—viz., when "approaching or receding from the poles of the field-magnets." Now, as a matter of fact, during this quarter of a revolution the bobbins are cut out of circuit altogether, that position being the weakest part of the field. The strongest is between the pole pieces. I shall be glad to see his machine described in "ours."

Humble Bee.

WATCHES.

[19823.]—IN reply to "Watch-Man" (19801), pocket chronometers have the usual detached chronometer escapements, cylindrical hair-springs, and compound balances. Half-chronometers are merely first-rate lever watches, with compound balances and isochronal hair-springs, very carefully adjusted for temperature and positions.

A regulator would be of little use in the above watches, for if they are of good quality, so small will be the error of their rates, that the ordinary watch-regulator would be far too rough an adjustment for them.

They are regulated by the alteration of the timing-screws. This is, I believe, a very delicate operation, which can only be performed by professional watchmakers, who have special dexterity and great experience.

Half-chronometers are usually keyless, and have no fusee; those of good quality have, instead, a tapered mainspring. Their "winding error" (if I may be allowed to use that term) is two or three seconds per 24 hours. The keyless mechanism of these going-barrel watches is very simple, and not easily put out of order.

Keyless watches, with going fusees, are made, but their mechanism is complicated, and liable to derangement. Chronometers are usually made to wind with a key, and have fusees. If they are properly adjusted, they have no "winding error."

Good English levers (not compensated for temperature) in use, treated with ordinary care, and uniformly (*e.g.*, not sometimes placed at night under a warm pillow, and sometimes on a cold dressing-table), the weather as regards temperature being moderately steady, will go with an error of about one minute per week.

The difference between summer and winter temperatures, however, will cause variations of five or ten minutes per week. I think the best way to answer the remainder of "Watchman's" queries will be to give him the rates of—first, a chronometer, very seldom worn, usually kept flat in its case, but exposed to variations of temperature; secondly, a half-chronometer, spring-tail lever, keyless with going-barrel, in wear, and placed flat on table at night. Both are of the finest workmanship, by E. Dent and Co.:—

Date.	Chronometer	Half-chronometer.
1881.	From Dent's cleaned.	
July 23 ..	G.M.T. ..	Going very irregularly.
30 ..	+ 10s.	
Aug. 6 ..	21s.	
13 ..	31s.	Sent to Dent's to be cleaned.
20 ..	46s.	
27 ..	54s.	

Absent from town. Took chronometer with me to North of Scotland.

Date.	Chronometer.	Half-chronometer.
1881.	From Dent's cleaned.	
Nov. 3 ..	— 41½s. ..	Received from Dent.
7 ..	47s. ..	G.M.T.
12 ..	50s. ..	— 5s.
15 ..	52s. ..	8½s.
19 ..	56s. ..	11s.
26 ..	55s. ..	15s.
Dec. 3 ..	1m. 2s. ..	19s.
12 ..	1m. 7½s. ..	22s.
27 ..	1m. 17s. ..	20s.
31 ..	1m. 16½s. ..	16½s.
1882.		
Jan. 7 ..	1m. 14s. ..	10s.
21 ..	1m. 16½s. ..	16s.
31 ..	1m. 19s. ..	25s.
Feb. 18 ..	1m. 6s. ..	23s.
25 ..	59½s. ..	21s.
Mar. 4 ..	50½s. ..	14s.
11 ..	43s. ..	11s.

From this table it appears that both watches are over-compensated. The chronometer gains 51s. in about a month in the warm weather in London, but it loses 98½s. in the cooler weather of Scotland in two months; it continues to lose until the end of January, but now it is gaining as the warmer weather advances. These watches have no secondary compensation.

Edward M. Nelson.

[19824.]—IN reply to letter 19801, below are the recent dates on which I took the rate of my watch (which I wear in the usual way) together with its daily rate:

	Slow. m.	s.	
Dec. 23, 1881....	1	43	....Daily rate.
Jan. 2, 1882....	2	1	.... 1·8s.
Jan. 10, 1882....	2	15	.... 1·7s.
Jan. 20, 1882....	2	32	.... 1·7s.
Jan. 30, 1882....	2	52	.... 2·0s.
Feb. 8, 1882....	3	12	.... 2·2s.
Feb. 21, 1882....	3	35	.... 1·8s.
Mar. 3, 1882....	3	52	.... 1·7s.

Rosicrucian.

TRICYCLES.

[19825.]—HAVING read with much pleasure the able discussion on tricycles, which has been going on in the "E. M.," I should like to offer a suggestion, subject to correction by "Our" practical ones. It has often struck me, when riding uphill, that an enormous loss of power occurs when struggling with the pedals just past the dead-centres, and that if we could reduce the leverage against us at that time we should reach the top of the hill with much less exertion. Could not this be done by making the toothed chain-wheels slightly oval instead of circular, and placing the longer axes at right angles?

Most of the writers in the "E. M." prefer the rotary-action to the lever; but a lever-motion, if well arranged, does away with the dead-centres, as each pedal reaches its highest point and begins to descend before the other reaches its lowest: a fact which ought to, and does, as far as my experience goes, place the lever before the rotary for hill-climbing. I, however, am looking forward to the practical application of doubling speeding as the real solution of the hill-climbing difficulty, and trust that the manufacturers' motto will be—

Onward and Upward.

REPLIES TO QUERIES.

**⁎* In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[44998.] — **Railway Continuous Brakes (U.Q.)**—In reply to "A Driver," I beg to inform him I have only seen his query on my way home from Calcutta, hence my apparent inattention. My hydrostatic brake was first run between Camden-town and Kew in 1853, and afterwards on the Shrewsbury and Hereford Railway in 1854 and beginning of 1855, when I left it to join H.M.S. *Cyclops*, in Black Sea. My brake is not self-acting, although it could be made so, nor would it in its present form act on bursting of tubes or breaking away of trains. But why should such things take place if properly made, and couplings tested as our cables are. I always contend the means to apply a continuous brake should be in the driver's hands, yet I provided for the guard doing so. Depend, if a universal brake is ever adopted, it will be some simple and inexpensive plan, and not the expensive and complicated ones now on trial. Having a brake that cannot be always depended upon is far more useless for public safety than the old ones used since the introduction of railways. I was in America in September last, and I examined some of the brakes used in that country. On the railway from Washington to Baltimore, the favourite brake is Longridge's air brake. The point with me when I introduced my plan, was a simple and inexpensive brake, as I well knew railway companies then would not spend their thousands as they do now on experiments, caused, no doubt, by Her Majesty's letter and the voice of her subjects.—EZRA MILES, Retired Engineer, R.N., High Wycombe, Bucks.

[45569.]—**Velocity of Water in Sewers.**—To "J. C. S. B."—Please show in plain figures how you arrive at the value of R (·567), and also of the area of flow, which you put down as 1·6 in your reply to the above in the 17th Feb. issue, and oblige.—SANITAS.

[45619.]—**Wave (U.Q.)**—I do not know about Channel waves in particular, but I give the substance of results collected by Professor Rankine from experiments by Scott-Russell, Thomas Stevenson, and others. (1) The utmost height of a wave in open sea is held by scores to be 43ft. Breakers 150ft. high have been observed on S.W. coast of Ireland by the Earl of Dunraven. The height of waves in deep water depends on their distance (or "fetch") from the weather-shore, where their formation commences. Mr. Thomas Stevenson gives the following formula as nearly correct during heavy gales when the fetch is not less than about six nautical miles:—Height in feet $= 1·5 \times \sqrt{\text{Fetch in nautical miles}}$. Mr. T. S. also gives the following table of pressures of waves, as observed by him, against a vertical surface, at Skerryvore:—

	Summer average.	Winter average.	Storms.
In lb. per sq. foot ..	611	2086	6083
In feet of water	9·8	33	97

"Subscriber" will find some further information in Molesworth's Engineers' Pocket-book. At the depth he mentions the water would scarcely be disturbed by the storm above.—GLATTON.

[45700.]—**Tools for Bending Iron.**—I send sketch of a tool for bending flat iron 1½ by ⅜.

FIG. 1.

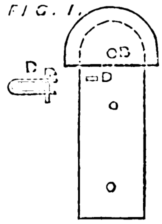


FIG. 2.

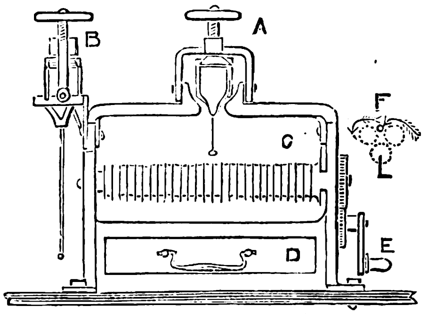
FIG. 3

Fig. 1 is bolted down to vice-bench, Fig. 2 is the lever, Fig. 3 is a side view of the lever, A is bolted on to *b*, and *c* is a loose wheel, *d* is a clip to hold the iron to bend.—CHEPSTOW.

[45823.]—**Oval Chucks (U.Q.)**—See answers to 46206.—JACK OF ALL TRADES.

[45823.]—**Oval-Chucks.**—Seeing no one better qualified has answered your query, I venture a reply. I think what you want is a copying-lathe, not an oval-chuck. If, however, you have a slide-lathe, you may easily add what you want, and could then do much useful work. You will want an overhead motion to drive a rotary-cutter in slide-rest, and an iron pattern of the handle you want to make. Fix this pattern at the back of the lathe-bed, and parallel with it, in such a way that it will make equal turns with the mandrel. Then fix to slide-rest an arm carrying a small roller to press against iron pattern, being kept up to it by a weight. The cross-slide of saddle must be slightly slacked, and the screw withdrawn. The rotary cutter will then move to and from the centre, copying the movements of the roller on the pattern. Put the leading-screw in gear with a slow traverse, move cutter up to its position, and you can make as many handles as you like. The shape of cutter is important; it must be well sharpened, and revolve at a great speed, and the work turn slowly.—F. A. M.

[45711.]—**Rotary Pill Machine (U.Q.)**—The sketch will give you an idea how this is made; it consists of a frame which two fluted rollers run in, C, with a draw underneath to catch the pills as they fall through; A is a press which the pill-mass is put in, and forced through a hole in the bottom, in which is one, two, or three holes a trifle less than the pill you wish to make; when the pipe is formed, lay it along the rollers, and turn the handle E until the pills fall through; F is end view, showing how they are geared; the rollers and press are generally gun-metal.—Jack of All Trades.



[45849.]—**Artist's Canvas (U.Q.).**—This can be bought at any artist colourman's, but if not to be got in your neighbourhood go to a draper's, and get some round threaded Holland—this is not callendered,—and suit yourself; it can be got of almost any grade. See that it is fine and even threaded; the flat thread is glazed surface, and when wet is gouty; for the other part see answer to 46119.—Jack of All Trades.

[45922.]—**Chrysoide.**—I presume this is a fancy name for one of the yellow metals which the Birmingham metal-workers know so well how to make. If so, it is mainly compounded of copper with the addition of zinc and tin. Manheim gold is copper 3, zinc 1, tin 5. A yellow metal for dipping is made in a roundabout way from bronze 2, copper 1, and a minute portion of tin. The bronze is made of 7 copper, 2 tin, zinc 3; and when the final mixture is made, 10 parts of tin are added to every 640 parts of copper. Most of the alloys of this class are made of the metals mentioned, but sometimes antimony and arsenic are also brought into use, but not where brittleness is to be avoided, in the case of the former.—Nun. Dor.

[45938.]—**Soldering.**—No doubt the series of notes on plumbing now appearing will contain some hints on lead burning or autogenous soldering, which is the highest branch of that part of the mechanical arts, so far as manipulation is concerned. It is accomplished either by pouring melted lead along the joint (rather into the runner formed in the sand covering the joint), or by means of the oxyhydrogen blowpipe (coal-gas and bellows). A good many failures will be made before success is attained, as much skill is needed in blowing long enough and not too long, the difference being a fraction of a second. On p. 356, Vol. XII., the old plan is well described; an article on autogenous soldering appears on p. 515, Vol. XX., and a useful reply on p. 559 of the same volume.—Nun. Dor.

[45943.]—**Pressure of Water.**—If the supply-pipe is a long one an increase of size would no doubt be beneficial. The meter would slightly check the flow. Use straightway-cocks in the supply. If the motor is of the right size, 36lb. to the inch would be ample to yield one horse-power.—Sunlight.

[45977.]—**Artificial Cable.**—The "artificial cable" used by the School of Submarine Telegraphy—now on view at the Crystal Palace—is a rather expensive and complicated piece of apparatus, or rather two pieces, for one part is used for providing sufficient resistance, and the other for imitating the effects of induction. A visit to the Palace would probably be the best way to get full information.—Sydenham.

[45986.]—**Refrigerator.**—Take notes from the refrigerators sold. Then make a double case of zinc, which stuff with sawdust or dry powder, such as charcoal. Line the recess in the wall with thick felt, spongy kind, three or four inches thick, and protect all doors by the same means. Of course you will put a drain in to take away drippings from the ice. and that may have a bend when outside the refrigerator so as to prevent air getting in.—Nun. Dor.

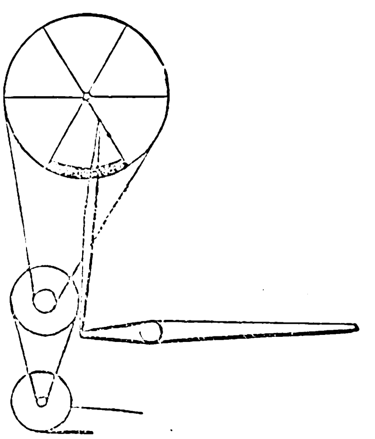
[46019.]—**Sausages.**—Two mistakes crept into my reply; for "flayed" read "hayed," that is, the herbs should be well harvested and of a good green, not black and musty, as generally supplied, and for "¼lb. allspice" read "¼oz." I have made some hundreds of pounds, for which our family used to get great praise, but the herbs and spice we could never get supplied with fit for use, so used to harvest and grind our own.—Jack of All Trades.

[46061.]—**Model Engine.**—To "Sunlight."—Being from home I cannot refer to the No. of the "E.M." which states the size of cylinder, &c. As I may be away for several weeks, kindly repeat dimensions of cylinder, and I will then with pleasure tell you what you want to know.—Sunlight.

[46069.]—**Automatic Arrangement.**—The printer has destroyed the sense of my suggestion as to this arrangement in last issue. For the sentence, "Projecting from lower side at middle of each division a pin or tooth-clack," &c., read, "Projecting from lower side at middle of each division a pin or tooth, clock to work a worm-screw which said teeth take into."—Scotch Working Mechanic.

[46082.]—**Driving Smith's Fan.**—I beg to say that being only an amateur smith, I have not had the chance of trying my skill on iron 4in. square, though I have welded more than half that substance. If "J. J. A." will come over here to Tramore, co. Waterford, Ireland, at any time of day and any month of the year, I shall be at home to show him the fan, and also show him how a fan can be blown with a pole, bellows fashion, which he fails to see, as he does many other things. Perhaps, in return, he will tell us how to weld a piece of hot to one of cold iron. Query: Did he ever do it?—J. Perry.

[46082.]—**Driving Smith's Fan.**—As "J. J. A." fails to see how I blow my fan with a pole, I have inclosed a rough sketch (¼in. to the foot) of the whole affair, and I can assure him that it is far from being a "bleak blasted blower," and instead of running at 500 per minute as he proposes, it runs much nearer 2,500 per minute with steady blowing. It runs much easier than anyone would imagine; but still, to keep at it as I have to, from 6 a.m. till 8 p.m., makes it hard work, and that is the reason I put my query. Many thanks to our obliging friend "Sunlight" for so clearly answering it.—Hot Iron.



[46089.]—**Muffle Furnaces.**—Can Mr. A. E. Morris say if such a furnace as that described by him on p. 620, March 3, would do for burning colours on plaques and small articles of porcelain; and, if so, what dimensions would be necessary for articles 12in. diameter and 4in. high?—W. Wilson, Hollingbourne, Maidstone.

[46094.]—**Paper Negatives.**—I presume that the calotype process for obtaining negatives on paper would suit "F. C.'s" purpose; but he will find no information in modern photographic books, as to the *modus operandi* of that process. The introduction of collodion has, by its superior sensitiveness and definition, rendered it obsolete; there are few of the present generation of photographers, I imagine, that have ever seen a paper negative. Nevertheless, it will render suitable subjects with charming effect, more artistic (to my mind) than collodion. The process is as follows:—Take 40 grains nitrate of silver, dissolve in three ounces distilled water, add 32 grains of iodide of potassium, well shake the bottle, and then allow the precipitate to settle. Wash the precipitate with two or three changes of water with agitation, then pour off the water closely and add 2oz. distilled water, in which 400 grains of iodide of potassium has been dissolved, shake up well, when the yellow iodide of silver will be dissolved, then add distilled water a few drops at a time, which will make the surface of the solution turbid, but it will clear again on being shaken. Add more water cautiously until the solution will no longer clear on being shaken, add a few grains of iodide of potassium with shaking, which will restore the transparency. It then only remains to filter, and it is then ready for use. The paper, which has been cut 1in. larger each way than the required negative, is then attached to a thin board by a couple of pins at the top edge, held in an inclined position, and the double iodide of silver and potassium applied to its surface by means of a large camel-hair pencil, mounted in quill (not metal), after the manner of applying a flat-wash in water-colour, taking care that the solution does not touch the pins or pass to the other side of the paper. There is no need to exclude daylight from the room in which this operation is carried on. Hang up to dry; and when perfectly dry, immerse the papers in a large pan of water, about half a gallon of water to each 10in. by 8in. sheet. Take care there are no air-bubbles attached to the surface of the papers, and leave them to soak for 24 hours; afterwards take them out and hang up to dry. If properly washed they will keep indefinitely in a portfolio. When required for use, attach to the board as before, and sensitise in a room lighted only by yellow light, by applying to the prepared (yellow) surface a solution prepared as follows:—Take nitrate of silver 50 grains, distilled water 6½ drachms; when dissolved add glacial acetic acid 1½ drachms (which keep in darkness); take gallic acid ¼oz., hot distilled water one pint; agitate well, and allow to stand 24 hours to sensitise; take 1oz. distilled water, 20 drops of above silver solution, 20 drops gallic acid solution, mix, and apply to the paper by means of a brush made of a piece of ½in. glass-tube, with a tuft of cotton-wool stuffed into one end. This should be applied copiously, first cross-wise, and then up and down the paper. Then allow the liquid to drain from one corner of the paper, and blot off the remainder with clean blotting-paper, taking care not to rub the sensitive surface. This must be done without a ray of white light entering the room. What remains of the solution must be immediately thrown away, and the glass containing it scrupulously cleansed for another operation. It remains then to attach the paper to a support for exposure in the camera. My practice has been to have pieces of glass cut to the proper size for the camera frames, and laying the sensitised paper upon some clean blotting-paper, face downwards, place the piece of glass on its back, fold over the edges, and by the application of gum-water, attach them to the back of the glass. When so secured, turn over and leave in a horizontal position for a few minutes, when the paper will have dried flat to the glass. A number may be prepared at the same time sufficient for the day's work, and made up into a packet. They should be placed face to face with a piece of clean blotting-paper of the same size between each sensitised surface. I change the papers in the field by means of a bag made of three thicknesses of black glazed calico, made large enough to pass over the shoulders down to the hips, with a square of yellow calico let into the front to admit sufficient light, and fastening round the waist with a piece of elastic band. The next thing is the exposure, the time of which, of course, depends on the light and the aperture of the lens in proportion to its focal length. A day in which sunshine and cloud alternate is the most favourable, for when sunshine continues during the whole of the exposure, the contrasts are generally too violent to be pleasing. On the other hand, a sky entirely clouded is apt to produce too little contrast of light and shade. This process allows some latitude in the time of exposure: from five minutes to a quarter of an hour is generally sufficient. Much depends upon the subject; it is best to err rather on the side of too long an exposure, than of too short. The plates with paper attached, when packed together, must be put in a flat box, impervious to light, to be conveyed to the scene of which you wish to obtain a picture. To develop the pictures, you take a piece of plate-glass a few inches longer and wider than the negatives, and placing it on a table, level it truly. You then take one of the plates from the box, and having laid it face downwards on a piece of clean blotting-paper, remove the paper by cutting round the glass with a penknife; then attach the negative to the sensitising board as before. Now observe the aspect of the picture as a guide to mixing the developing solution. This is composed of aceto-nitrate of silver as previously prepared for sensitising, but without any addition of water, and the solution of gallic acid. If no trace whatever of the picture be visible, mix the aceto-nitrate and solution of gallic acid in equal proportions. Should the sky and high lights of the picture be slightly browned, add two parts of aceto-nitrate to three of gallic acid. Should the sky and high-lights be very strongly out through great over-exposure, add one part of aceto-nitrate to three of gallic acid. This mixture must be made in a perfectly clean glass, and applied to the picture with a brush made as before directed, with clean cotton wool, passing it rapidly over the picture, beginning with the sky, bringing it down with a flowing edge to the bottom, taking care to leave no spot untouched. The quantity required for 10 by 8 picture will be about one-third of an ounce. In a minute or two the development commences; then repeat the process with gallic acid alone. Use the same brush and glass, and apply the gallic acid copiously; first longitudinally, and then transversely. Now pour some gallic acid upon the middle of the glass slab, and spread it by means of the brush just used. Remove the picture from the board, and lay it face downwards upon the gallic acid on the slab. The development, which should now be rapidly advancing, must be carefully watched. When the dark parts of the picture begin to appear through, it will be time to lift it up and examine it against the light. The development should not be arrested until the details in the deepest shadows are fully out. Be very careful not to wet the back of the negative with the developing solution, and also in the previous stages not to touch the sensitive surface with the fingers. When the development is complete, lay the negative face downwards on the surface of clean water in a dish, which change once or twice. All this must be done in a yellow light, or by the light of a rushlight or small benzoline lamp. To fix the picture, make a strong solution of hypo-sulphite of soda in water, in which immerse the picture until the yellow iodide of silver is thoroughly dissolved out, which can only be ascertained with certainty by daylight. Finally, wash the picture in abundance of common water, changed several times, then leave it to soak in water for several hours, in order to remove all traces of hyposulphite, and hang up to dry. Before printing from the negative it should be waxed, which is easily accomplished by taking an earthenware dish with upright sides, which stand in another larger one, into which pour boiling water. The negative is then placed on the bottom of the inner dish, which should previously have had a cake of clean white wax rubbed over it. Then rub the wax over the negative both front and back. The heat will, in a short time, cause the wax to thoroughly penetrate the pores of the paper. Care must be taken that the negative is quite dry before waxing; also that water does not get into the inner dish. Many negatives may thus be waxed together in a short time. When they are thoroughly penetrated by the wax, take them out singly and hang up. It remains now to finish them by ironing between sheets of blotting-paper with a moderately-hot smoothing-iron, until no shining patches of wax remain on either side. Care must be taken not to crease them in the process of ironing. It only remains to say a few words on the paper best adapted for negatives. The French papers are not good, being sized with vegetable matter; a gelatine-sized paper is requisite. Five-and-twenty years ago there were papers in the market specially made for the purpose. Hollingworth's negative was very good. I myself preferred Turner's; I do not know if these are obtainable now. I am not acquainted with Morgan's. I have some of the proper paper still, and would send a sample for experiment on receipt of address. I prefer printing from these negatives on plain (ammonium) salted paper, or a paper prepared with serum; albumenised paper I think altogether unsuitable.—AN OLD PHOTOGRAPHER.

[46100.] — **Lever 'Scapement.** — "Lock and Draw" must not, no, nor anyone else, follow the advice given on page 13, No. 885, as he will most certainly get his 'scapement out of angle, and out of upright, too. The 'scapement after such treatment would have to be repitched all through. The banking-pins would be wrong, and so would the hole through the pallets and lever that pin them and keep them in angle. It would be difficult for a good workman to succeed in this, equipped with necessary tools. If the 'scapement is nowhere else faulty, perhaps opening the one banking-pin might relieve it enough. Should the 'scapement only be slightly shallow in the 'scape-wheel and pallet-depth, it might be cured by slipping on the roller-staff a slightly larger roller than the present one—or less alteration still may do; set the roller-depth deeper—or just take off the present roller, place the same on a fine piece of steel, and hold it near the flame of a very small lamp, just to warm it, taking care not to blue it, and carefully *set out* the *ruby-pin* just a trifle, that will probably carry the pallets far enough in the 'scape-wheel over the rocking-faces. The advice given not to alter the faces of pallets is good. If you do the job as there specified you will certainly ruin the watch, and perhaps have to have an entire new 'scapement. No one could successfully do such a job without the ability, and the help of a good depth tool, and upright tool, or a mandril.—T. FREEMAN, Nuneaton.

[46118.]—**Slide-Valve and Piston.**—If the slide-valves leak, the only way is to take them out and examine the valve-face. If the face is not cut or scored, you may be able to put it to rights again. You would first want a perfectly true surface-plate, and to this you would have to file and scrape the slide-valve so that it bore all over. Then using it as the surface-plate, get up the valve-face to it. But if the face is cut or scored at all, it will need planing, which you will need to get done. —SUNLIGHT.

[46122.]—**Hydraulic Ram or Water-Wheel.** —I should say, by all means use the hydraulic ram for the purpose E. Hurley requires. Working fall, 6ft.; height of ascension-pipe and water to be elevated, 40ft.; quantity to be raised in 24 hours, 50 gallons; quantity per minute, ·0347 gallons; diameter of bore of drive-pipe, ·375in.; length of ditto, 40·80ft.; inclination of ditto, 1-11·50; diameter of orifice in seat of arresting-valve, ·5625in.; drop of arresting-valve, ·0933in.; number of blows or strokes of arresting-valve per minute, 39·5; area of the discharging orifice between the arresting-valve and its seat, when the water is flowing therefrom, ·1646in. The drive-pipe here given is the medium, or best length for this particular working fall and ascension-pipe elevation. It may, however, be for minimum length 32·60ft., and for maximum length 49·00ft. The quantity proposed to be raised—50 gallons per day—is very small. I find that at least 30 gallons per day should be calculated for general purposes for each individual residing in the house, and it is far better to have 50 gallons per head per day, bearing in mind, for good sanitary results, that the water-closets and sewers should be kept clean, and all fæcal matter carried away to a distance. I would therefore suggest to E. H. to lay down an inch ram, with a drive-pipe the length previously stated, and a bore of 1in. This will raise about seven times the quantity he named (50 gallons), —350 gallons per day, and ample for a house containing from seven to ten residents. The difference in cost would be very trifling: for instance, you can purchase of the importers a $\frac{3}{4}$in. ram for 36s., 1in. for 44s., $1\frac{1}{4}$in. for 56s. I refrain from mentioning names of persons and places, that my reply hereto may not be considered invidious, or an attempt to advertise. No doubt the publisher of the "E. M." will be pleased to insert an advertisement in the regular way of business for E. Hurley. I may further inform E. H. that the number of makers of hydraulic rams in England may be counted upon the fingers of both hands. Their several kinds vary in successes and failures, as well as in principle. Some put them down by "rule of thumb." Hence there are many failures, with sometimes a chance of success. Others, I believe, go into the matter thoroughly and scientifically with good results. You will find in the "E. M.," from the earliest date, this matter has been written on and discussed, up even to the present time. The late Professor Rankine wrote sundry articles upon it in the *Engineer*, Vol. XXXIII., pages 55, 84, and 163, in 1872. In the first two pages quoted he gives certain empirical rules, which I fear are of little value, except as incentive to a further investigation and study of the subject. In the last article, p. 163, he gives the mathematical theory of Venturoli, who, I presume, was an Italian. In the 9th clause he says, "In the present state of our knowledge it is impossible to determine the values of K^2 V^2, except through experimental trials of actual rams." In his steam-engine and other prime motors, p. 211 and 212, the subject is treated of very concisely; certain empirical formula are given, which may be possibly of use in a particular case. These are the only English writings on the subject that I am aware of. The earliest patent I can find is by Boulton and Watt, No. 2207, dated Dec. 30, 1797, price 1s. The next by Montgolfier, jun., No. 3992, dated March 14, 1816, price 10d. A London firm is reported to have obtained a patent at a much later date. I, however, have been unable to trace it in my search through the Patent Office Publication of Specifications. D'Aubriesson, in his "Traité d'Hydraulique," gives an article upon the Hydraulic Ram, with tables of the heights, quantities, and co-efficients of useful effect of those made by the Montgolfiers, father and son. Also of a portion of the experiments by the savant, Eytelwein, who made 1,123 experiments in investigating its construction. This is the best and most voluminous article that I know of published on this subject. These experiments were made 1804, and no doubt, with our better mechanical knowledge and principles of construction, we ought to succeed beyond that attained nearly 80 years since. Those who succeed best in England, as well as those who sometimes succeed, keep the manner of laying down "a trade secret." I do not condemn them for it. Even Prof. Rankine, before quoted, was unable to obtain sufficient and reliable data in his investigation. Still, it is to be done, and is done. The different makers vary considerably. In the bore, length, and inclination of the drive-pipes, even when working under the same height of fall and vertical height of ascension-pipe, in diameter as much as 2· to 3·, and area as 4· to 9·, so that within certain limits a fair result may be attained. But it will not do to copy a particular case, and consider that all others should be exactly in the same proportion. Each particular working fall and vertical height of ascension requires a certain length of drive-pipe. It should not be more nor less than a specified length; so is its diameter of bore regulated by the gross quantity of water (run to waste and elevated) and the working fall.—TUBAL-KAIN.

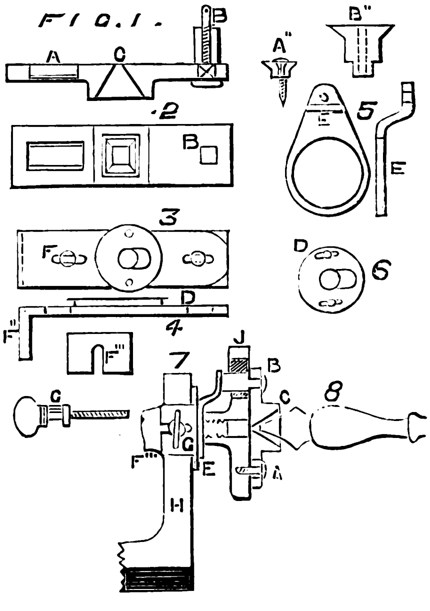
[46132.]—**Fluoric Acid for Soldering Iron.**—It is to be hoped that the querist will not waste time and money in making the "mess" given on p. 14. The recipe is a very old one, and is often given by "old hands" to greenhorns. Like many other gifts, it is parted with at its full value, though, strange to say, it appears in a modified form in Spon's "Receipts."—NUN. DOR.

[46148.]—**Fret Saw and Lathe.**—Thanks to Mr. Hoskin for his reply. I want to cut mahogany $1\frac{1}{4}$in. My flyweel is 29in. in diameter. Is not the saw inconveniently near the upright? I think of putting bearings on the latter, and so bringing the saw a couple of inches further out.—J.

[46162.]—**Nascent Oxygen.**—Many thanks to "Analyst" for his answer to my query, and promise of further information. I did not intend to ask how to obtain nascent oxygen by decomposing chlorate of potash with manganese. But how to safely decompose it when mixed with the black oxide, for the purpose of liberating a larger quantity of nascent oxygen than is obtainable by the usual practice of saturating the black oxide alone with sulphuric acid, diluted to about 60 Twaddell. I have long practised the latter mode of obtaining nascent oxygen for the purpose of bleaching oils, and fats, but as chlorate of potash contains more oxygen than the black oxide, I am anxious to know how it can be treated so as to obtain the best result for my purpose.—J. P.

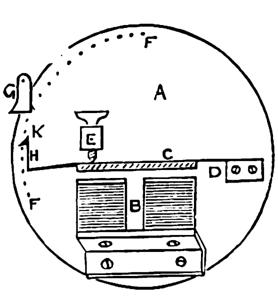
[46171.] — **Electric Communications.** — If "Motion Plate" could visit the Crystal Palace Electric Exhibition, he will see working models of Stroudley's patent train communications, at Messrs. Garnham and Co.'s stand, 144, Eastern Gallery.—PEGANREDSTUFF.

[46206.]—**Oval Chuck.**—I suppose your mandrels come such a little way through your headstock that you have no room for the fittings. If if you have 5-16ths of an inch between your face-plate boss and headstock, you will be able to get this arrangement in; but if you have not more than an eighth of an inch, you can dispense with the adjusting slide F. Fig. 1 is a piece of either wrought-iron or cast, best wrought-iron bar $1\frac{1}{4}$in. by $\frac{3}{4}$in., shouldered down as shown, to $\frac{3}{8}$in. thick at both ends. There is a slot at A, and a square hole at B, and a taper-square hole at C; this is the slide. The flush side is next your face-plate A″ is a small guide-block to be fitted in A. B″ is another fitted in the slot in face-plate and square hole B, and fastened up to the shoulder by the long screw, the end of which comes through and forms the connecting pin for eccentric strap; 2 is the front view; 3 is the adjusting plate upon which the eccentric is screwed; 4, side view of same; F″ is the end, shown again at F‴, with a



slot into which the screw G engages by the double collars; this screw is screwed into the edge of hood and stock for adjusting eccentric to what is required: 5 is the eccentric strap; 6, eccentric; 7, the whole in position in section, with handle turned; I is an ordinary driving-chuck or face-plate. If you dispense with 3, fasten the eccentric with two screws upon lathe-head and slots in the eccentric for adjusting. The wood you wish to turn should be tapered down to go into the taper hole in the slide; the eccentric adjusting slide and strap make out of 3in. No. 10 B.W.G. hoop iron. When the whole is fitted, make a pan about 2in. deep of tin or sheet iron, get ¼lb. vegetable black, and take equal parts of the white ash, sifted very fine, from under your grate, ¼oz. prussiate of potash; dissolve this with 1oz. of table-salt, and mix your ash and vegetable black up like mortar; line your pan, and pack your things in it, with a layer between, and the holes filled, and plaster all over to keep the air from them; place them on the top of kitchen-fire, and get them to a red heat, and keep them at that for an hour or two, when take them off and bury them in the ashes, or in some sand, and you will find them very hard without distorting them. Do not slake them in water. This will give you a good oval chuck, with little trouble or expense, with which you may turn any tool-handles or hammer-shafts.—Jack of All Trades.

[46208.]—**Electric Clock Dials to Beat Minutes.**—I am making one as follows, and have every reason to believe it will answer well :—A,



wooden disc fitted to turn freely on pivots, and to carry minute hand; F, brass pins (60) round edge of do. about ¼in. long; B, electro-magnet receiving current every minute from primary clock; C, soft iron keeper; D, spring; E, stop screw (not in electrical connection); H, a piece of very flexible steel; K, brass triangular hook. The magnet acting on the keeper once a minute draws it down, and moves the disc on the distance of one pin; when keeper is released the hook, K, falls over the next piu ready to act upon another current being sent; G is a stop hanging loosely on pin to prevent the hook, K, from turning back the disc. The hour hand is worked from the minute hand, as in an ordinary clock.—H. A. Dawkins.

[46209.]—**Photographic.**—As this has only been partially answered by Mr. Lancaster, perhaps you will allow me to supplement his reply. There would be no difference in light transmitting power betwixt pot and flashed colours if of the same tint; but I may tell "No Sig." that practically pot ruby is unknown. I have seen samples of it, but it is not a trade community. There are difficulties in the way of manufacture; secondly, pot colours are in all cases lower in price than flashed or stained; but any such price as 2s. per foot is simply extortion. The best ruby can be bought at 8d. per foot, and second quality at less than this. Of course, in country places, it would be dearer, but even then 2s. is far too much. It might be information for your correspondent if I add that three kinds of coloured glass are made—pot, flashed, and stained. The difference being—pot is coloured throughout, flashed is a thin film of coloured metal blown on white glass at time of blowing, and stained being burnt in afterwards. Blue is to be had pot and flashed; ruby, flashed only; green, pot and flashed; purple, ditto; opal, ditto; yellow and orange, pot and stained; stained red, stained only. —E. Holmes.

[46211.]—**Engine for Driving Lathe.**—To "Sunlight."—Very much depends on the work to be done. I would not advise less than a 3in. bore and 6in. stroke engine at least. Length of cylinder inside, 8in.; thickness of piston, 1½in., packed with Ramsbottom's steel rings; walls of cylinder and steam-chest might be ½in. when cylinder is bored, the steam-chest being that thickness in the casting; steam-chest, 4in. long and 3in. wide inside; steam-ports, ⅜in. wide and 2⅜in. long; bars between the ports, ⅜in. wide; exhaust-port, 1in. by 2⅜in.; steam-pipe might be, if short, ¾in. in the bore; if any length, 1in.; exhaust-pipe, 1½in. bore; slide-valve, 2¾in. by 3in. wide; exhaust-port in valve, 1¾in. by 2⅜in. wide; eccentric with ½in. throw, and consequently giving valve 1in. travel; crank-shaft, 1½in. diameter; flywheel—if space available, 2ft. 6in. diameter; if limited for room, 24in. may be used; weight, say 50lb. As to governors, that must depend on the class—whether of the old Watt form or high-speed ones.—Sunlight.

[46217.]—**Model Electric Engine.**—As I have made several models of electric engines, I beg to offer "W. F. C." a description of one. A^1 A^2 are magnets made of soft iron 2½in. long, covered with No. 22 wire, which are placed 5-16in. apart; B is the beam 4¾in. from C to D, and 3in. from C to B, worked by E 2½in. from B to E; at E the keeper is placed 1¾in. by ½in. (Fig. 2); F is the contact breaker, 1¼in. long; G is the connecting-rod, 1in. long; H is the flywheel, 3in. diameter; I I the flywheel standards, 3in. high; J J the beam standards, 3in. high; K is 7in. by 4in. Fig. 3 is a section of the contact-breaker, and mercury cups M M M connected by N to E. The engine works by the magnets pulling alternately. When the current runs through the magnet A^2 it draws the keeper E towards it, when the contact is broken by one wire of the contact-breaker being lifted out of the mercury; the flywheel then carries it over the dead point, when the other wire of the contact-breaker dips into the mercury on the other side, when magnet A^1 is connected and draws the keeper to it; the flywheel then goes over the dead point again, and so on. This engine works admirably with one Bunsen. The parts can be made twice as large, and a small pulley-wheel can be placed on the flywheel. The beam, standards, and contact-breaker are made of wood or any suitable material.—R. W.

FIG. 1.

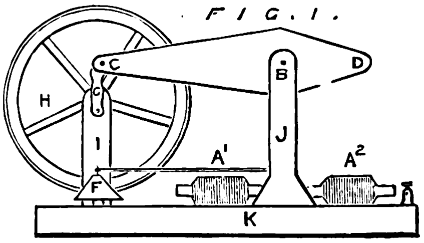


FIG. 2

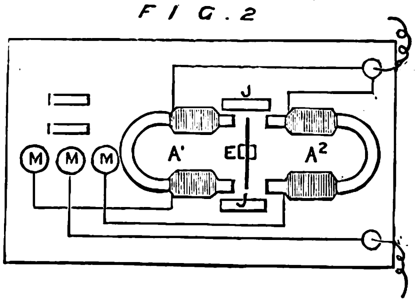

FIG. 3

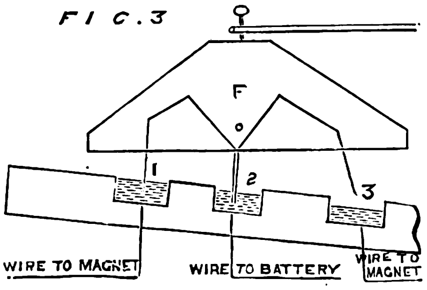


[46222.]—**Link-Motion.**—Your query is not very precise. You should give the dimensions of the steam-ports, and other elements of working, as explained in my answer to query 46220. You will perhaps get the information you want by reading it. From what you say, if I understand right, you have begun wrong. The throw of eccentric cannot be determined before you know the link you are going to use. The rocking-shaft will simply give to the slides a motion reverse of that of the eccentric-rods. The radius of curvature of link is 3ft. 3½in. − 1¾in. = 3ft. 1¾in., as said in above reply. The link's length has also been mentioned in the same reply. All such dimensions are dependent upon the room you can dispose of for them in your engine. It is a very unlucky idea to use a straight link with the same gear. You will not secure any of the advantages of the curve link, and besides it will not work symmetrically. Adopting Allan's straight link will be a very good plan, and answer quite as well as the shifting link; but it requires a long distance between the valve-face and the engine-shaft, and it is not simpler in construction, save that it is not curved, but it is not a gr eatsaving of trouble.—E. Gobert.

[46225.]—**Steam-Launch.**—I should consider the 3 h.-p. Cochran boiler, good as they undoubtedly are, too small for a 4 h.-p. nominal engine as your 6in. cylinder would be, and therefore it would be hardly possible to get the full power out of the engine. I, therefore, could not tell you what speed you would get with a boat 28ft. by 6ft. 6in. beam; but, looking at the dimensions generally, perhaps as much as six or seven miles per hour. The lines of the boat would greatly influence the speed. Thus I could put such lines into a boat that with the dimensions you name the engine-power as stated would give, say, a speed of eight to nine miles; yet, with the altering of lines, same engine and boiler should not drive the boat as much as six miles an hour. I should decidedly also advise you to have the next size boiler if you intend to run up to 300 a minute. It really is not fair to expect the 3 h.-p boiler to do it, as it could only be done by forcing it for a short time, and shortening the life of it thereby.—Sunlight.

[46234.]—**To "Peganredstuff."**—You could hardly attempt a more difficult task. The sort of escapement referred to is about the worst and most defective principle ever brought out. The impulse received being only once in two vibrations, is hardly enough to overcome the immense friction of the swing arbor pivots and light pendulum. Experienced hands are often puzzled what to do with them. I will, however, give a few suggestions in the matter. If much cut, it would be better to make new pallets, taking care to have as little drop inside and out as is safe, left as hard as possible, and the acting surfaces well polished. As I have observed, these timepieces are very delicate, it is necessary you should see movement quite clear. Have mainspring out, and be sure that is also clean, and oil with good oil, both mainspring, all holes, and escape-wheel teeth.—Peganredstuff.

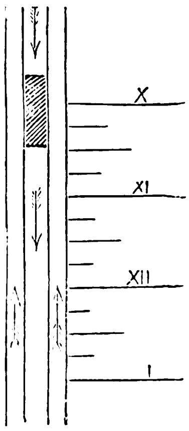
[46237.]—**Lithography.**—F. W. Thomas need not be much surprised that his sketches will not print if they have been left aside for a considerable time. The cause of failure is the action of air on the printing-ink, the gum having failed to keep it out. The remedy in such a case is to dissolve away the old ink, by means of turpentine, and to "rub up" with fresh ink. In doing this, the less of the gum rubbed away the better, as it performs good service in preserving the white parts of the stone. In some cases I have seen benzine substituted for turpentine, but in either case the sketches will "rub up" as good as ever.—D'Evlyn.

[46248.]—**Amateur Dramatic Club.**—"A Fellow Workman" does not say how many his company numbers, or whether he has any means of making any scenery, &c.; but I should suppose his company would be rather limited, and, of course, he must choose his piece to suit. Unless he can obtain the help of a few ladies, I am afraid his choice will be somewhat limited. I will suppose he is able to do so. He will find a very good farce, in one act, for three males and four females, in Mr. J. L. Toole's great piece, "Ici on Parle Français." It is very good throughout, and very funny, if the part of Spriggins is well played; and requires no expensive costumes or scenery. I should say it would be very suitable. Then there is another I can recommend, for three males and three females; a very pretty piece, indeed, and also very funny, if the part of Paddles be well played. It is a comedietta, in one act, entitled, "Which is Which"; time, present day; so no costumes or expensive scenery are required for it. Then there is a roaring comedy in "Checkmate," by Halliday, in two acts, for seven males and five females; only it is a little more extravagant, and takes more getting up; the scenery, also, is more elaborate, but it will pay you well for getting up if properly done. Then there is the well-worn, but ever good, "Box and Cox," a farce in one act, for two males and one female. Now, if this piece is not worn out in your country, I can strongly recommend it as easy to get up and exceedingly funny, with some very nice acting in it, especially poor old Mr. Buckstone's favourite character, Mr. Box. This also requires no scenery nor costumes. By playing one long piece and one short one, you can make a very nice evening's amusement. There is a very good short piece for two male characters, in "A Most Unwarrantable Intrusion," by S. M. Morton; it is a farce in one act, and takes three-quarters of an hour to represent. It is exceedingly funny, and a splendid piece altogether. Caution—whatever you do (unless you have been well used to acting in public a long time), do not try to get up a drama or tragedy piece, as nothing is more painful to the audience and annoying to the performers, than either done badly, and it is wonderful what a lot they do take doing. Then you will want wigs, whiskers, moustaches, paints, &c. In ordering a play you must ask for the *acting* edition of the play you want.—W. Lissington.

[46263.]—**Porous Slabs.**—Plaster of Paris is a bad substitute; better buy the porous slabs to be obtained so cheaply, when their durability is taken into account.—W. J. Lancaster.

[46263.]—**Porous Slabs.**—Thirteen years' experience convinces me these are the worst batteries in use. You had far better have single cells joined up with wires or bands of copper: troughs are rarely ever water-tight between the partitions and difficult to clean; a syringe is required to draw off and replenish them. Plaster of Paris for porous plates will not do at all, it gradually dissolves in a Daniell's (at least I have found it so); Wedgwood ware plates are sold, but it is very difficult to secure them in a trough, and they are quite as dear as porous cells if of good quality.—An Associate of the Society of Telegraph Engineers.

[46267.]—**Curious Clock.**—There are two glass tubes, one within the other; the inner tube contains mercury and also atmospheric air; at each end, the inner tube communicates by a small orifice with outer tube, and consequently the mercury in its descent has to force the air out of the inner tube to the outer, and thus the rate of descent is regulated, the descending arrow in inner tube is the air forced downwards by the weight of the mercury; the air escapes by the small orifice, passes into the outer tube, and ascends in it, as shown by the two lowermost arrows; when it reaches the top of the outer tube it enters the small end of the inner tube, and thus as fast as the air is forced out below, it enters above, as shown by descending arrow above the mercury; outer tube is hermetically sealed.—Peganredstuff.



[46277.]— **Refractors.** — The oldest form of erector was one in which three lenses formed the whole eyepiece; the results are not nearly so satisfactory as the present two-lens eyepiece and two-lens erector. I have, during the last week, had a peculiar eyepiece, in which the eyepiece proper consisted of an arrangement of four lenses, but nothing that I know of equals a well-made erecting eyepiece of four lenses in all.—W. J. Lancaster.

[46282.]—**To "Sunlight."**— The theoretical pressure on the cylinder of a gas-engine I should not like to express an opinion on—it might be most misleading. Neither do I think it is worth while to go to theory when practice tells us all we want to know. You ask me what is the actual pressure? Well, it varies with the strength of the mixture. But a properly-designed engine should use such a proportion of air and gas that the maximum average pressure should be about 190 to 200lb. on the square inch. I have had as much as 210lb., and as little as 27lb. A good motor using compressed mixture should develop about 200lb. as a maximum. If we go much over that, the pressure and temperature border on line over which many practical difficulties crop up. Although I should be quite prepared to design and supply an engine to give pressure as high as 350lb. to the inch, I have all the information needed to do so, but there are details that would be likely to suffer under the great pressure, at least with engines at present in use. No doubt the pressure in the cylinders of gas-engines will be increased in time. And I am also sanguine that in a few years we shall have gas-engines with cylinders no larger than steam-engines of the same power. And knowing these facts, I may add that I am already considering the question of increased pressures. But until I see my way clear on several points which would be prejudiced by mere pressure, I shall be content with an actual pressure of about 200lb. on the inch.—Sunlight.

[46286.] — **Geneva Watch Cleaning.** — If "Darius" will refer to a recently-published letter of mine, he will, I think, find something instructive as regards watch-cleaning. In the letter referred to I gave instructions how to clean a lever watch. What is there written will apply, in great part, to a Geneva. First of all, after taking the movement out of the case, and removing hands, dial, cannon-pinion, &c., place a bristle, or something fine and pliant, in the escape-wheel, unscrew and remove the cylinder and its bar, withdraw the bristle, and let the watch run down. If the watch has a "bar" movement, the spring may be let down (if not already down), by putting a key on the square, firmly held, and easing the click out. After this, unscrew the 'scape-wheel bar, and the other bars, or plate (if a ¾ plate), in regular order. After all has been cleaned, and the holes carefully pegged out, replace each part as it was before, oiling after it is put together. When you clean the cylinder you must exercise great care. Turn the stud of the regulator half-way round, so that the hair-spring may pass out from between it and the pin adjacent to it; take hold of the bar in the left hand, and let the cylinder hang freely down. With the nippers take a firm hold of the hairspring stud and ease it out of the bar. After cleaning the bar and pegging the jewel-hole, slightly oil it; clean the cylinder from dirt, or anything that has attached to it, and replace as before, not forgetting to turn the regulating-stud over the pin, with the hairspring free to play between. The escape-wheel teeth should be touched a little with oil. A portion on two or three teeth will suffice. I here take the opportunity to correct an unintentional error which I made in the letter previously referred to—i.e., as regards the quantity of oil required to a pivot. I then stated that only as much oil should be applied as would make a spot on paper, as large as any full stop in my letter. I had in my mind's eye a larger stop than was actually to be found there. However, very little oil, comparatively speaking, is necessary. Having, then, replaced the cylinder, put in the set square and affix the cannon pinion to it; fit the motion-wheels, dial and hands, set in case, and wind. Respecting cylinder pivot fitting, an amateur would have to be particularly skilful to do this job satisfactorily. First, remove the hairspring and collet, then drive out the old plug with a suitable punch, and shellac an arbor over the body of the cylinder, filling the hollow so as to make it perfectly rigid. If you have a roughly made plug and pivot, fit it into the cylinder and with the "turns" a horse-hair bow, and suitably shaped gravers and pivot files, shape and reduce as may be required. The new pivot must be made perfectly free in the jewel hole, and you must observe to get the correct "end-shake." The plug must not protrude inside the cylinder, but should be left flush with the notch. It is a very delicate operation, and requires not a little skill to do properly, so unless "Darius" is prepared for a fidgety and somewhat difficult task, I would advise him to send his cylinder to a jobber accustomed to this class of work. The ferrule may be removed from the cylinder by soaking in spirits of wine.—Alfojoe.

[46289.]—**Cleaning and Relacquering Brass Chandeliers.**—You, of course, know everything depends upon having the brasswork free from grease or dirt: unless you are very careful on this point, you will never get the work a good colour. Perhaps the better way for you to accomplish what you want will be to boil the brass parts in a strong solution of pearlash until apparently clean, then place them into a vessel containing a solution of aquafortis, about one of acid to three or four of water; let them remain in this solution for an hour or so, afterwards washing them well, and scouring, if necessary, with sand until every part is clean, then make up a solution of equal parts of nitric and sulphuric acids, and add to it about one-third part extra of nitric acid, having zinc dissolved in it in the proportion of about one zinc to three acid. When boiling dip the articles in until they have the colour you require; 20 to 30 seconds will be ample. Then swill well in plenty of water, and place all the parts in fine sawdust until dry. When dry you can rub up with soft rags and a leather, and when just too hot to hold, lacquer the whole of the parts that will be at all exposed. When going through the process above, take care not to handle any part of the brasswork; and, above all, do all the work out of doors, or in a place with a large chimney, to take away any fumes of nitrous acid, which are most deleterious to the lungs.—W. J. Lancaster.

[46293.] — **Electro-Motor.** — I am pleased "A. A." has been so successful in making the motor. Now he will be able to make the motor go quicker by adding more battery power. He has evidently wound his electro-magnet successfully, otherwise it would not hold so much weight; but strength of current and speed of revolution go together, and any speed can be obtained by adding more cells. The armature should come down as closely as possible on to the cores, so as to leave scarcely room for a piece of paper to go between when passing each other; then the slightest alteration in the position of the commutator will make all the difference in velocity, and he might with advantage put on eight armatures, and make a wheel for commutator with eight divisions instead of the six, as now. I shall give every particular as to weight of wires, &c., in papers on coil-making.—W. J. Lancaster.

[46294.—**Thermo-Electricity.**—To "Sigma."—I have not seen the article referred to, and have not any details specially bearing on the subject. But I know that some time since great things were expected from metallic sulphides, and more especially from galena and sulphide of silver. I made some experiments which did not induce me to go any further. In fact, I do not believe in any good results likely to arise from substances having high resistances, nor do I expect real useful work will ever be done in this way by compound substances whose molecular condition is liable to be modified by heat. In fact, tempting as the direct conversion of heat into electricity looks, there is really no practical success attained in this direction. Noe's battery seems, on the whole, the most advantageous, chiefly from the form of its construction.—Sigma.

[46296.]—**Harmonium or Organ.**—I have a large harmonium to which I thought of adding a second manual on the American system. I had had the tubeboard some time, and was making American organ. After considering the great space required for two separate sets of reservoirs and feeders, concluded it best to keep to the American plan. If your reservoir is large, you may have four "feeders" and reservoirs in half the space required for the exhaust and force bellows combined. With regard to adding more reeds to the present instrument, if "Beta" will advertise his address I will inform him how I am designing to accomplish the same without an additional set of pallets. But as some weeks will elapse ere I can test the idea, it had better become an accomplished fact before appearing in print, or would have sent. —D.

[46297.] — **To Mr. Lancaster.** — There are plenty of lathes that would help you much in making a motor; for instance, the table below, which is reduced from Sprague's excellent work on electricity, would be invaluable to you if committed to memory, and what now seems to be an insurmountable difficulty can be easily overcome. You will be compelled to believe the seller's word as to the conductivity of wire supplied, or spend a lot of money in apparatus for testing yourself. The former is the more practical method, and in nine cases out of ten may be relied on. I shall be pleased to give any further information you may require.

B. W. gauge.	Ft. per pound.	Ft. per ohm.
12	27·32	1170·6
14	46·28	691·0
16	78·24	408·8
18	132·22	241·9
20	206·60	154·8
22	322·81	99·1

—W. J. Lancaster.

[46298.]—**Glycerine.**—This can be made from the alkaline mother-liquor of the soap-works (from which the soap has been separated by means of common salt), by neutralising with sulphuric acid, removing the excess of that acid by carbonate of barium, evaporating the filtrate to a syrup, digesting it for several days with alcohol, separating the alcoholic liquid from the $NaSO_4$, which crystallises out, decolourising with animal charcoal, again evaporating to a syrup, exhausting the residue with strong alcohol, and finally evaporating the filtered solution over the water-bath. A more economical method of separating glycerine from spent soap lyes is that patented by H. Reynolds. The liquid is first reduced by evaporation, and raised nearly to the boiling-point, by being passed through a heated still-like vessel, or heated in any other convenient vessel. It is then passed into a second vessel, where it is met by jets of superheated steam, at a temperature of 380° to 400° Fahr., which raises it to the boiling-point and evaporates the glycerine, carrying the vapour upwards with it, and leaving the salts to deposit in the vessel. Commercial glycerine may be contaminated with lead or lime. The former may be detected by sulphuretted hydrogen, the latter by dissolving the glycerine in its own volume of alcohol, containing 1 per cent. of H_2SO_4, in which case, if lime be present, a precipitate will be formed. It is also often adulterated with sugar, which may be detected and estimated by means of chloroform, in which glycerine dissolves with ease, whereas cane-sugar and glucose are quite insoluble. The liquid is first heated to expel the water contained in it, then mixed with chloroform; the whole is then poured upon a tared filter, and repeatedly washed with chloroform, after which the filter with its contents is dried at 212°, and weighed.—F. BARKER COOKE.

[46299.]—**Precession of the Equinoxes.**—Any astronomical work of any importance will give both the annual precession, and the amount that precession has accumulated to. Since the formation of the earliest catalogues on record, the equinoctial points have receded among the stars 30°, which is equivalent to one complete sign of the Zodiac, and the amount of this retrograde motion is 50·1″ per annum. Now, by a very simple calculation, we can find when the sun was in Aries at the Vernal Equinox. Reduce the 30° to seconds, and it will equal 108,000″ then ÷ 50″ (taking round numbers), which is the annual precession, and this shows us that it is about 2,160 years since the sun was the same degree in Aries that it is at present in Pisces at the Vernal Equinox. This brings us to the early days of astronomical record. If "Astrologos" can find the exact number of degrees that the sun is in the sign Pisces, then by the same method of calculation he will be able to find "when" it first entered that sign. Precession was discovered by Hipparchus, the celebrated Greek astronomer, about 150 B.C.—A. MANOCK.

[46299.]—**Precession of the Equinoxes.**—If "Astrologos" would study and master the effects of Precession, he would be able to answer his question, because he would understand better than anybody else what it is he wants to know. It is not more difficult to understand the theory of precession than any other simple astronomical phenomenon. Let him carefully examine a globe and remember that the equinoctial point recedes along the ecliptic at the rate of 50·1″ per annum. By an easy process in simple arithmetic, he will then be able to find its past and future time and place all round. He will find the constellations, as such, are not equally divided along the Ecliptic, and also that a part of "Cetus" intervenes between Aries and Pisces, so that, in point of fact, "the change" directly "from Aries to Pisces" never did take place at all. The equinox, since it first entered the "constellation" Pisces, has already moved along 28 degrees nearly; therefore: As 360° : 28° : : 25,868 years (the time it takes to go right round) to 2,012 years ago, since "the sun first entered the constellation Pisces at the Vernal Equinox." This is only approximately correct, the exact time being, probably, something short of 2,000 years ago.—DRACO.

[46300.]—**Broken Drills.**—The easiest way is to measure very carefully and get the exact place of hole on other side of plate, drill a rather smaller hole to meet point of broken drill, and drive it out with a wire or small punch. I have often had the same happen. If there is any of the broken drill you can get hold of with pliers, you can sometimes, by heating the brass, which will expand more than the steel, loosen the drill and draw it out. But often the cutting-edges are imbedded, and so the drill cannot get loose. The one fault of the Morse drills is their tendency to break in the smaller sizes and in deep holes. They have not "relief" enough at the back, and so work tight after getting a little way in.—TREADLE.

[46301.] — **To "Sunlight."** — Simplest form would be an externally-fired one, say 24in. long, 6in. diameter, with a good dome about 4in. diam. and 4in. high. If made of 3-16ths plate, should stand anything up to 60lb. or 70lb. with the greatest safety. That is with ends riveted in properly. Your ¾in. bore cylinders should stand 45lb. steam, if they are properly made. Six screws would give enough holding power if they were properly tapped in.—SUNLIGHT.

[46303.]—**Medical Coil.**—To MR. LANCASTER.—It is not often I have a doubt as to the real meaning of a query. Yours, I apprehend, has reference to a coil in which the primary and secondary are both different circuits. In that case, the secondary is insulated from primary, and the two ends of secondary go to the handles to be held by patient. The primary is coupled to battery, one wire going direct to one pole of battery, the other going through vibrator to the other pole of battery. This wire is broken when the vibrator is pulled towards the bundle of wires inside primary.—W. J. LANCASTER.

[46304.] — **Hardening Brass Wire.** — You might perhaps render it elastic by placing a steel mandril inside the spiral and then dressing the outside well with a light hammer. I know of no other way of making brass springing. It may be rendered hard and brittle by being heated red-hot and cooled slowly.—GLATTON.

[46306.]—**Telephone v. Bell.**—1. The magneto current generators are far superior to batteries, and are maintained at less expense. 2. If you use a transmitter, two or three cells at each station would be required; this would dispense with magnetos. 3. Any form of indicator will do if the coils are of suitable resistance. 4. You can ring two bells at the same time. 5. The sound produced would be as loud as the electric, as the magnetos could be made powerful enough to melt the bell coils. 6. I have known the Leclanché cell remain effective for four years without requiring water or sal-ammoniac during that period. The best form of magneto is one with a Siemens armature placed longitudinally between the arms of a powerful magnet. If you are near here, call, and I will show you one.—GEORGE TOLMAN.

[46308.]—**Telescope.**—To MR. LANCASTER.—The lenses belonging to your opera-glass will work their best as they are for astronomical purposes. Just look at the cluster of the Pleiades or pick up any part of the Milky Way—you will be able to count three times the number of stars you can see with the naked eye. The focus of your lens is too short to be of any value with convex eyelenses. As it is, with its concave eyelens, it forms a sort of small Galilean telescope.—W. J. LANCASTER.

[46311.]—**Horizontal Engine.**—See my reply to query 46211. For boiler, if externally fired, you might use one 4ft., or 4ft. 6in. long, by 1ft. 6in. diam.; firegrate, 15in. by 12in. I am supposing that you do not do any excessively heavy work in the lathe, and that it runs fairly easy. Slide-rest must depend on what is the construction of lathe-bed, and if to be hand-traversed, or self-acting in all directions. Let me know what you want, and I will endeavour to help you.—SUNLIGHT.

[46312.]—**Repairing Cylinder Face.**—What you want is to get the valve-face planed in place. There are many firms who would do this, as there are several forms of machines made to bolt on and do the job, being driven by hand-power. Some years since I designed such a machine purposely for cases like yours, where the steam-chest does not come off at the valve-face level. The slide-valve of course you can easily get off, and get it planed and scraped up again all right. I am sorry I cannot afford you more assistance than what I have stated above.—SUNLIGHT.

[46313.]—**Roof for Lean-to Hot-House.**—I put up a lean-to about the same size as "Muscatel" requires. In the roof I have a mid-rib on which I placed rafters of ⊥-iron 1in.; painted them one coat red-lead, and glazed with 21oz., each pane cut round at bottom. This makes a light and yet strong roof, and cheaper than wood. If "Muscatel" will advertise his address I shall be glad to give him full particulars and plans.—C. R. T.

[46314.]—**Closet-Cistern.**—Examine the air-pipe which comes up from supply-pipe to the top of cistern; most likely it is broken off about half-way down, and when the water reaches the top, where it is broken off, it runs down the air-pipe into the supply-pipe. You can put a new leather on the valve by unscrewing the nut close under the leather, and have an air-pipe from trap, as the foul air will come up when the pan or valve is shifted.—JUMBO.

[46314.]—**Closet-Cistern.**—There is usually a bent pipe in the cistern to get the fullest effect from the rush of water upon the opening and shutting of the valve, and possibly you have bent this down somewhat whilst fumbling at the valve. In order to fit a new leather empty the cistern, place a spanner on the squares of the valve-seat and unscrew it, disconnect from the wire, re-leather, and replace.—J. J. A., Liverpool.

[46315.] — **Ethoxo Limelight.** — This light appears to me to be a great improvement on the spirit form in use, as a better light can be got. I have been trying various experiments with it to get a perfect light and also a simple form of apparatus. But I am so much from home that my experiments have not been concluded. If "Exhibitor" can let the matter rest for a week or two, I hope to bring my experiments to a finish, and will then better advise him. I have now some three or four plans, but think I can still further improve them, or at least one of the best. The mixed gas-jet can be arranged to work with it; but a special jet is far better. As to hydrogen-generator, the one I use stands in a small cabinet, and acts splendidly; but it is not on the wash-bottle plan. Two glass vessels stand one over the other, the bottom one containing the hydrogen, as also the zinc cuttings. The upper chamber holds the acid and water, only the pressure of the gas as it is generated drives the acid solution into the upper vessel, thus giving a fine pressure. I pass the hydrogen, which is then under a pressure of over 24in. of water, through a regulator on the top, which allows it to pass to the lantern at a pressure equal whatever is wanted to balance the oxygen-bag, or oxygen-generator, as the case may be.—SUNLIGHT.

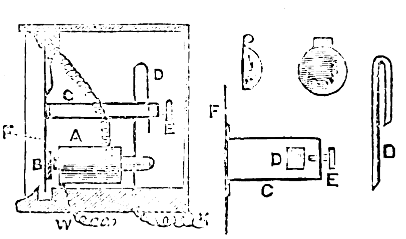
[46317.]—**Ferns.**—Allow the fronds to dry between paper in a book under slight pressure; then when dry, coat them with blacklead, put on damp, allowed to dry, and then polished gently with a tuft of cotton wool. See that the blacklead is all over the frond, otherwise the deposit will be in patches. You might carry a wire down the centre of the back of the frond, then you would be more likely to have a good coating of copper all over.—W. J. LANCASTER.

[46317.]—**Ferns.**— "Single Cell" can obtain beautiful electrotypes of ferns and leaves thus:—Take a sheet of letter-paper and rub it slightly with sweet oil all over; wipe all the oil off, so as to leave only a greasy surface; lay the frond, back downwards, on the paper, and after spreading it out properly, cover with a piece of blotting-paper, and press flat for a minute or two; this will grease the leaf and prevent adhesion. Now turn the leaf carefully over, and then with a camel's hair-brush cover leaf and paper with melted wax, brushing over layer after layer. Make the wax-cast pretty thick, and stick a penny or two on the back to make it sink, waxing over the pennies. Then carefully pull paper and frond off the wax, and a beautiful impression will be left, which blacklead and immerse in the usual way. Proved many times.—B. H.

[46318.]—**Protecting Steam - Pipes.**—Make hay ropes about 3in. circumference, wrap them close round steam-pipe; coat this with at least 3in. or 4in. of puddled clay, mixed with plasterer's hair or cut hay to keep it bound together. This I have tried with a long steam-pipe, underground, and found it most effectual in retaining heat.—ATKINSON.

[46320.]—**Motor.**—When you say you desire a motor, what sort of one have you in mind? From being a movable affair, a water-motor would not be admissible. Clockwork would be not of much service, as it would need to be wound up before it would actuate the weight? How long at a time do you need the power? It will be a difficulty; but perhaps if you give more particulars I may be able to help you.—SUNLIGHT.

[46322.]—**Electric Sign.**—I send a rough design for this, which I hope will answer your purpose. A thin sheet of metal F is fixed by its upper edge to a box, the other edges being free, so that it can vibrate, pendulum fashion. Holes are cut in this, and little concave reflectors (as shown below) are suspended in these by their upper edges, which are formed into simple hinges. Thus, if the plate F is made to oscillate, all the pendant discs vibrate in their respective holes. To obtain this oscillation, an electro-magnet A is fixed to the box, and opposite to it is an armature B, which forms part of plate F. A strip of brass, C, is bent as shown below, and attached to F. A screw, tipped with platinum, E, passes through it, and when the apparatus is at rest presses on a piece of platinum soldered to the end of a brass spring, D, which forms one of the terminals to which the battery is connected. The spring D is shown below separately. The curly lines show connections. The battery being connected with the two wires shown at base of box, the current enters at W, passes through magnet to top of F, thence by C to E, and back to battery by D and X. The action is similar to that of an electric bell. The spring D, particularly the upper part, should be weak.—GLATTON.



[46323.]—**Pumping by Steam.**—Far better to sink a well at hand than to attempt to connect an 8-h.p. engine to a well 200 yards distant.—J. J. A., Liverpool.

[46323.]—**Pumping by Steam.**—Your query is not particularly clear; but I take it that what you want is to first pump the water from the well for the engine feed-pump to draw from. Now it all depends on the levels. If the lift is but trifling, an ejector could be easily made to draw water from the well, and deliver it into a tank close to engine. If that cannot be done by reason of the weight of lift, then it remains for you to adopt one of several plans: one would be to drive a wire rope off the engine to actuate a pump at the well, and so get the water to the engine feed-pump. Another would be, if the vertical lift is not more that 28ft. or so, to use a vacuum pump, as they are sometimes called. A cast-iron vessel is connected at the bottom end with the well by pipes, and to the steam space of boiler at the top, proper valves and stopcocks being fitted to the iron vessel and to the water and steam-pipes. Steam from the boiler having been admitted, and the air expelled from the iron vessel, the steam admission is closed, and a vacuum quickly forms. Water from the well then flows in, fills the vessel partly. By turning on a stopcock to the tank the water now flows out by gravity, and the operation is repeated; or sometimes I have seen the apparatus placed above the water-level of boiler, and hence the water is fed direct into it Would either of these plans suit you?—Sunlight.

[46325.]—**Intensity Coil.**—1. It depends on the resistance of your primary coil, and ditto the secondary. 2. A coil giving 2in. or 3in. spark is sufficient for vacuum-tubes, exploding gunpowder, &c., &c.; you must look out, for the other purpose, one of the best induction-coils you can obtain, but do not attach this to the tubes, or you will require a good supply.—George Tolman.

[46325.]—**Intensity Coil.**—There is no exact ratio between cell-power and size of coil, but an average of 1 quart Bunsen to every 1-5in. spark will be about as much as it is well to use. (2) You will not get a coil that will enable you to heat a piece of platinum-wire; the current from the cells alone will do this, and fire gunpowder with a fuse. The coil will, however, help you in firing powder. You should get a coil that will give what we call a fat spark, and see that the coil gives the length stated by the vendor before you purchase it. (3) The calcic protosulphide CaS does phosphoresce when just made, and should then be put into a glass tube and hermetically sealed.—W. J. Lancaster.

[46328.]—**Lodger.**—By the Lodgers' Goods Protection Act, 1871, when the superior landlord distrains or threatens to do so, the lodger must make a written declaration claiming and describing his property. and must give this to such landlord or his bailiff. He must also state that the rent due from him has been paid, or if not he must then and there tender it to the superior landlord. If, after being served with this declaration, he still distrains, the distress will be illegal, and the lodger can apply to the nearest police magistrate for an order for the recovery of the goods, which order, upon proof of the declaration, will be made against the landlord.—Fred. Wetherfield, Solicitor, 2, Gresham-buildings, Guidhall.

[46329.]—**Chromate of Calcium.**—I have never had occasion to prepare this salt; but if required only in small quantity, I should prepare it by neutralising a solution of chromic acid with lime. If "W. T." requires it in large quantities, and will write again, I will do my best to devise a convenient and economical method of preparing it. —Analyst.

[46329.]—**Chromate of Calcium.**—This is obtained by dissolving calcium carbonate in aqueous chromic acid, or as a light yellow precipitate, by mixing concentrated solutions of chromate of potassium and calcium chloride. Also by roasting chrome ore, in fine powder, intimately mixed with chalk, grinding the roasted mass with water, and adding sulphuric acid until the liquid has an acid reaction, in which case dihydric calcic chromate is formed, and remains in solution. Calcium chromate ($CaCrO_4$) is moderately soluble in water, insoluble in alcohol, gives off its water at 200° C., and is afterwards very sparingly soluble. The anhydrous salt is used as a pigment.—F. Barker Cooke.

[46330.]—**Cream Separators.**—I do not know if this is what you want, but the sketch illustrates the principle of a cream separator. Imagine a "wheel of life," or Zœtrope, with the slots filled up, and a flange round the edge projecting inwards. This being filled with milk is set in rapid rotation, which by centrifugal force causes the milk to stand up against the sides. Enough milk is poured in to just touch the edge of flange, and the speed is increased and kept up for some minutes. The milk being denser than the cream is thrown outwards with greater force and displaces the latter, the two being separated into two layers, of which the inner one is composed of cream. (See Fig. 2.) When the separation is complete, a portion of skim-milk (the amount of which is regulated by experience) is added, and this flying outwards displaces its own bulk of cream, which escapes over the edge into a trough which surrounds the apparatus, and shown in section in Fig. 2.—Glatton.

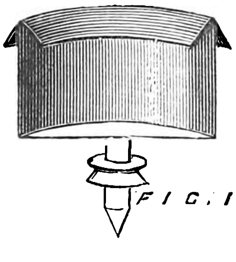


FIG. 1.

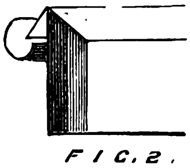

FIG. 2.

[46332.]—**Electrical Resistance.**—Water offers the highest as far as I am aware. I believe a glass tube, filled with water, 12in. in length, offers as much resistance as the Atlantic cable. Wheatstone's Bridge and galvanometer.—George Tolman.

[46332.]—**Electrical Resistance.**—Every textbook gives the information asked for. Common distilled water gives a very high resistance, so do alcohol, turpentine, or any liquids not subject to electrolytic decomposition. The methods and instruments required are the Wheatstone bridge, or differential galvanometer and measured resistances, which involve a long description to be found in every book on the subject.—Sigma.

[46333.]—**Gregorian or Cassegrain.**—Supposing spherical curves are used, the small "concave" in the Gregorian form violently magnifies the aberration of the large mirror. The small "convex" in the Cassegrain form partially corrects the aberration of the large mirror. The "flat" of a Newtonian does not affect the aberration of the large mirror, but simply diverts the cone of rays. The radius of the small "convex" in the Cassegrain form may be from ¼ to ⅛ of the larger concave. In Vol. XXXIII. are several letters on the "Cassegrain," including two from myself, giving a rule for determining the distance between the mirrors when the radii are given, pages 116 and 209. If "G. L. E." had given the distance between the mirrors, I would have suggested an approximate radii for them.—A. N. H.

[46334.]—**Gas Purifying.**—We do not know the arrangement of "Rosicrucian's" small gasworks; but in order that the purification of gas may be effectual, it is essential that the gas, after passing the hydraulic main, pass on to the condenser, washer, and, finally, the lime purifier. After the gas has passed through the washer, a great amount of its impurity has been extracted; but that it may be better fitted for use, and freed from the remaining impurity with which it is contaminated, it is passed through what is known as the lime purifier. This purifier consists of a large air-tight veessel in which are arranged a series of perforated trays in a horizontal position. On each of these trays is a layer of slaked lime, which the gas is brought in contact with, and thus divested of the remaining sulphur impurities. After this, the gas may be conveyed to the gasholder, and considered fit for use. With reference to the quality and purity of gas, this will depend upon the class of coal the gas is obtained from. London gas, which is principally made from English coal, gives a light equal to that of fifteen sperm candles, while the gas in Edinburgh, which is made from the Scotch Cannel coal, gives a light equal to, I believe, thirty sperm candles. The fact is technically expressed by saying that London gas is fifteen candle-gas, while that in Edinburgh is thirty candle-gas. The rate at which gas is burned when its illuminating power is being determined, is five cubic feet per hour, and the flame thus produced is scientifically compared (by means of suitable apparatus), with that of a sperm candle, whose rate of burning is 120 grains per hour. If our querist is wishful to obtain a large quantity of gas, he will find Cannel coal to answer his purpose; but, of course, he will also find it more expensive. —A. Manock.

[46335.]—**To Mr. Lancaster.**—You may use the permanganate of potash in boiling water, if you wish. The heat will not affect the permanganate to any extent; but if any infected clothing is placed in the solution, the action of the permanganate is very rapid; but, at the same time, it will be as equally effective as with the other clothes in the cold water.—W. J. Lancaster.

[46336.]—**Telephone Circuit.**—If "Meme" will say what telephones he proposes to use, whether receivers only or a receiver and transmitter at each end, I will show how to connect it as he wishes. Any simple switch arrangement will suffice to cut the bells out of circuit and place the telephones in connection with the line and batteries. It needs only for a connection to be made between both telephones and bells, with the line and batteries at each respective end, and then to insert a switch which by turning a key (or similar arrangement) will break the connection between bell battery and line, and join up the telephone with battery and line, or *vice versâ*, at will.—F. C.

[46336.]—**Telephone Circuits and Calls.**—Some time ago I described just the thing you want; but you can easily make a simple switch with as many ways as pieces of apparatus to be used. Thus Stud No. 1 might put bell in circuit; Stud No. 2 put telephone in, and 3 microphone. You can, if you like, have telephone in circuit with microphone, and the mere hanging of the telephone on to a hook throws in the bell; then by lifting off the telephone, a little spring lifts up the hook, and will throw telephone and microphone in circuit.—W. J. Lancaster.

[46337.]—**Steam Launch.**—To "Sunlight." —First let me ask you, have you at least three square feet of grate surface in your boiler? I should hardly think you have. Heating-surface also is entirely too small. I should want, for such an engine, at least 30 square feet of heating surface, and more if possible. It depends on the class of boiler. It is possible in a boiler but little larger, if any, to get the required surface. A Cochrane boiler would do so in the size nearly. I write this from home, therefore cannot refer to makers' lists. But, at any rate, the boiler you name is too small.—Sunlight.

[46338.]—**Sulphide of Calcium.**—This substance may be prepared by passing a current of hydrogen sulphide over quicklime heated to redness in a glass or porcelain tube, until it ceases to be absorbed; or, if the presence of a little free carbon is no objection, by heating a mixture of two parts of calcium sulphate (plaster of Paris) and one part of finely-powdered charcoal to redness in a Hessian crucible. The crucible may be covered, but vent must be left for the escape of the carbonic oxide which will be evolved.— Analyst.

[46338.]—**Sulphide of Calcium.**—This can be made (1) by passing sulphuretted hydrogen gas over lime ignited in a porcelain tube, water and calcium sulphide being formed, as $CaO + H_2S = CaS + H_2O$; (2) by decomposing the sulphate at a red heat with carbonic oxide, as $CaSO_4 + 4\,CO = CaS + 4\,CO_2$; (3) by strongly igniting dry sulphate of lime in a charcoal crucible, or with one-third of its weight of charcoal: 100 parts of ignited gypsum, heated to whiteness in a charcoal crucible, yield 51·52 calcium sulphide, $CaSO_4 + C_2 = CaS + 2CO_2$; (4) by igniting pure lime, or its carbonate, with half its weight of sulphur in a closed vessel, $4\,CaO + 4\,S = 3\,CaS + CaSO_4$.— F. Barker Cooke.

[46338.]—**Sulphide of Calcium.**—You have evidently been making or trying to make CaS_5, the calcic pentasulphide. You, I suppose, want to make the calcic protosulphide CaS, the phosphorescent salt. Canton made it from oyster-shells in an impure form by putting the shells in an open fire for half an hour, then allowing them to cool; and picking out the larger and whiter pieces, he packed them with one-third their weight of flowers of sulphur in a crucible with a cover luted on. This crucible was heated for an hour in a hot fire, and eventually the phosphorescent sulphide was taken out, broken up, and hermetically sealed in glass bottles. The best way is to put it in glass tube flattened over, and seal the ends up.—W. J. Lancaster.

[46339.]—**Dynamo-Machine.**—You evidently mean for two 20-candle power incandescent lamps. I shall shortly be able to give you this information, as I am making up several sizes of dynamo-machines for one, and any number of such lamps. —George Tolman.

[46339.]—**Dynamo-Machine.**—It is possible to make such a machine, but at present there is not a good and simple form of machine to be within any amateur's ordinary means. I have been at work for some time with motors and dynamos, and shall, I hope, have something good and simple before long.—W. J. Lancaster.

[46342.]—**Estimation of SH_2 and CO_2.**—Gas-liquor does not give off SH_2 or CO_2 when boiled with lime, as both these substances would be fixed by the lime. If it is the SH_2 and CO_2 in lime which has been used for the purification of coal-gas, that "L. D." wishes to estimate, I shall be glad to describe the process, if he will write again.— Analyst.

[46343.]—**Smith's Fan.**—In reply to Albert Hall, I hope to have all dimensions, with sketches, made out for you by next week, unless you communicate with me by post, as I am afraid the particulars will take up too much room. You will see my address in reply 46082.—J. Perry.

[46349.]—**Model Steamboat.**—I am not able to refer to my file of the "E.M." for the reason stated in reply 46337, or I could refer you to the woodcut and all information with pleasure. You want a boiler about 8in. or 9in. long, and 4½in. wide, the height being, perhaps, 6in. to 7in. But a reference to back numbers would give you the desired information, as I have given all details several times.—Sunlight.

[46349.]—**Model Steamboat.**—I am at present making a tin boat, 4ft. in the keel, 9in. draught, and 7in. beam. Her boiler is of copper, about as thick as strong note-paper; length 9in. by 3in., having a flue of 1½in. at one-third from the bottom, and fired with benzine, mixed with paraffin oil; boiler is riveted with round brass tacks and then solder-sweated. I use no safety-valve, but in the piece of short tube for supplying her with water, I stick a small cork, and this will be blown out ere the boiler bursts. The lamp is filled up inside with cotton wool, and then takes half-pint of benzine. This gets up the steam well.—J. J. A., Liverpool.

[46350.]—**Lantern Optics.**—There will be no appreciable difference between the colours. A simpler experiment is an ordinary coloured lantern-slide: all the colours have the same focus, and if one is in focus every other colour will have the same focus precisely; this is very different to ordinary chromatic aberration. A series of circles painted on the glass slide, the centre being violet, then I, V, G, Y, O. Red outside will produce a concave on the screen and, *vice-versâ*, a red centre and violet circumference will produce a convex on the screen.—W. J. LANCASTER.

[46351.]—**Leclanche Battery.**—The white deposit formed is an oxychloride, not an oxide, and the only way of preventing is the thorough saturation of the carbon with melted paraffin, by means of a prolonged soaking at just over the melting point.—SIGMA.

[46351.]—**Leclanche Battery.**—The cause of the oxide forming on the lead cap is on account of the salts creeping. You should have the carbon-plate 3in. above the porous cell, and soak in paraffin wax one half the length of plate. All the Leclanché carbon-plates that I have seen are too short.—GEORGE TOLMAN.

[46351.]—**Leclanche Battery.**—Heat the top of the carbon until the lead begins to soften, then plunge the carbon to a depth of at least 1in. in boiling paraffin; leave it in the paraffin for half an hour, then remove and put in cell: this will prevent the creeping up for a long time, and when bad do them again.—W. J. LANCASTER.

[46352.]—**White Fungus on Fish.**—I have seen it stated that this fungus is caused by overcrowding, and that it can be removed by sponging the fish with a strong solution of salt-and-water, immediately replacing it in fresh water, and repeating next day, if necessary. A note to *Land and Water* would be sure to elicit a scientific reply.—ROSICRUCIAN.

[46352.]—**White Fungus on Fish.**—All the information on the subject up to August, 1880, "C. O." will find in detail in the report on the disease which has recently prevailed among the salmon in the Tweed, Eden, and other rivers in England and Scotland, by Messrs. Buckland (late), Walpole, and Young. The Blue-book, 1s., may be had from any of the Queen's printers. The latest theory as to the origin of the fungus was, that it is the outgrowth of a parasitic worm invading the fish. This theory was published in *The Scotsman* a few days ago, and signed by a surgeon, who presumedly had studied to some extent botany and zoology before leaving college.—W. ADAMS.

[46354.]—**Telephone Transmitter.**—I have tried this form of microphone, and could get no better results than yourself. If you require a good form of transmitter I will send sketch of one. The primary of induction coil is inserted between battery and microphone, the secondary one end to line the other to telephone, the other end of telephone to earth or return wire. I have been unable to perceive any gain with the coil. The intensity of three cells is better than the quantity of one passed through the primary, which soon polarises the cell. I have known the Blake transmitter fail with a half-hour's conversation, on account of the cell becoming exhausted.—GEORGE TOLMAN.

[46356.]—**Analysis of Alloys.**—It would take much more room than the editor would allow to answer your query properly. You will find full particulars in Fresenius's "Quantitative Analysis," and in Bloxam's "Laboratory Guide."—F. BARKER COOKE.

[46357.]—**Clock and Watch-Making.**—To "ALFOJOE," &c.—I am very pleased to give "No Trade" a few words of encouragement in his laudable desire to learn a little of the watchmaking craft at even so late an age as thirty years. It is confessedly very late in life to set about learning a new trade; but I am able, from my personal knowledge, to speak of two instances where young men have forsaken the calling of their earlier days, and have become in one case very proficient in the trade, and in the other actually a skilled workman, and now in possession of a large and lucrative jobbing and sale trade. In the latter instance, the young man who, as an intimate friend of mine, is necessarily well known to me, had not, at the age of 22, so much as taken a watch or clock to pieces. Only twelve years have elapsed since he made the new departure; but having a taste for mechanical pursuits, he bent his whole energies to the work, practised self-denial in a most remarkable degree, as he gave up a lucrative but objectionable calling, and received little or no salary for nigh upon two years in return for the instruction he received. Having made a change and pushed on well in two subsequent situations, he started in business for himself in a small way, and has since made an increasing and uninterrupted success of it. As regards the former instance which I spoke of, the young man was a paperhanger, but had, in his spare time, "pottered" with clocks, &c. When his apprenticeship expired he applied himself wholly to clock working, and used occasionally to assist in the same house in which I was then working as watch-jobber. He, too, when last I heard of him, had a business of his own, and was doing fairly well. So "No Trade" will see that it is possible for him, if he is prepared to practise patience and perseverance, and, above all, a little self-denial, in a pecuniary sense, to be that which he desires. If you have a friend in the trade, or, if not, can make one, and obtain the desired help or counsel, lose no time about it. Strike while the iron is hot, and take as your motto, "Nil Desperandum."—ALFOJOE.

[46358.]—**Galvanometer.**—The galvanometer referred to by "M.M.I.Sc.S." is a horizontal flat coil non-astatic galvanometer. It is wound with very fine wire to a resistance of about 1,200 or 1,300 ohms. It is used with the Wheatstone bridge, for which purpose it is well adapted, being very sensitive and portable. The dial is graduated with degrees. The maker is Elliot. The pivoting is jewelled, if I remember rightly.—HUMBLE BEE.

[46360.]—**Roofing.**—Port Dinormic slates, 14in. by 8in., or 16in. by 10in., hung on two galvanised malleable hammered nails. Nothing would look so well as slates. Cost per square of 100 yards about 190s.—J. M. CALLUM.

[46361.]—**Bicycle.**—The idea that "turning back the extremities of the fork," for say 2, or even 3in., would elasticise it, or that it would travel anything straighter is a baseless one. What strain would be eliminated? The saddle could be advanced one step to the rear, were the backbone itself not so curved.—J. J. A.

[46365.]—**Income-Tax.**—I think "J. W.'s," difficulty has arisen from the way in which he has made his return. The amount of his pension and appointment should have been set down separately and paid upon, while the deduction should have been made from the remainder. Had he done this, then, beyond the £40 pension he would have shown only £170, and taking the allowed £120 therefrom, there would have been £50 left, which, with the £40, would make the £90 on which he has paid. There is no doubt that lately the "screw" has been put on the income-tax, and officers finding out omissions have made the most of them. "J. W." should return carefully next year.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[46368.]—**Clock.**—Try the back, having removed the three screws through the case near the front, and you will find it turn a little way in one direction. Having turned it as far as it will go, by a little manœuvring it will come out, bringing the works and face with it. The setting-stud will come off; the winder generally is pinned on tight. I was puzzled the same as you till I found out the bayonet-catch that keeps the back in place.—TREADLE.

[46369.]—**Vacuum Tubes and What Can be Done with a Coil.**—As, I think, I stated in my answer to "W. R. C.'s" original query, I shall be pleased to send a few articles on "What to Do with a Coil," including a description of vacuum tubes, and an account of the truths which may be gleaned from experiments with them. I have not done so yet, partly because of pressure of other work, partly because the offer having until now passed unnoticed, I concluded that the subject was hardly of sufficient general interest to warrant our editor in finding me space.—ALFRED W. SOWARD.

[The proffered series would be most welcome.—ED.]

UNANSWERED QUERIES

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last, Ezra Miles has replied to 44998; Glatton, 45649; Jack of All Trades, 45711, 45849.

QUERIES.

[46371.]—**Barlow Lens.**—Would some correspondent kindly inform me which lens in the achromatic combination Barlow lens is crown-glass; which flint, and which should be placed towards the object-glass of the telescope?—X. Y. Z.

[46372.]—**Classification of British Beetles.**—I shall be much obliged if anyone will inform me where I can find a good classification of the British Coleoptera? I have "Common British Beetles," by the Rev. J. G. Wood; but the classification in it is rather confused, though, in other respects, it is a most useful work.—A LADY ENTOMOLOGIST.

[46373.]—**L. & S.W.R. New Coupled 6ft. 6in. Bogie Engines.**—To "METEOR."—Can you inform me how many of the new coupled 6ft. 6in. bogie express locos., built by Peacock, there are on the L. & S.W.R.?—WYKEHAMIST.

[46374.]—**Gauging Water.**—Can any reader inform me of the mode of calculating the discharge of water through the rectangular-stepped notches used in brooks for gauging the variable flows? I have abundance of formulæ for the individual rectangular notch, but I fail to find any for the stepped notch.—G. A.

[46375.]—**Steam Trap.**—Can any reader inform me, from actual experience, of the best steam trap or siphon in use?—G. A.

[40376.]—**N.B.R. & L.B. & S.C.R. Engines.**—Will some correspondent give the distribution of the weight of the following engines?—North British Railway 6ft. 6in. bogie express, "Abbotsford" class, and 6ft. bogie tanks by Mr. Drummond. London, Brighton, and South-Coast Railway, "Grosvenor," and six-coupled tanks (Terriers). Also the wheel-base and distribution of weight of "Abbotsford" and "Grosvenor" tenders?—MOTION-PLATE.

[46377.]—**Electro-Motor for Tricycle.**—Will anyone kindly tell me if any electro-motor in conjunction with a secondary battery has been arranged for driving a tricycle? and, if so, what weight is thereby added to the machine, and what speed is attainable?—R. E. B.

[46378.]—**Bevel Wheels.**—I wish to drive a machine by treadle, with two bevel-wheels. What I should like to know is, which would run the lightest—a 6in. wheel into a 3in., or a 12in. into a 6in.? I wish to run the vertical shaft twice to the horizontal shaft once.—BEVEL-WHEEL.

[46379.]—**Gramme Dynamo Machines.**—Would "Sigma," or some other electrical authority, kindly help?—We have several of the above-named machines at work in our works for electric lighting. On several occasions they have become so hot as to char the covering on the wire of the revolving parts. Would too hard pressure of the brushes cause this? Should they only touch lightly on the revolving copper plates? The person in charge of them says, when they touch lightly, the fire flashes freely from them, and they become hot; but I incline to think the brushes are pressed too hard up to their work, and produce heat through excessive friction. Sometimes the machines are covered with copper dust. One got so hot, that the wood insulators on the spindle went on fire. Would imperfect insulation between the wire and the spindle cause this?—NORTH BRITON.

[46380.]—**Electric Human Skull.**—Will any of "ours" give me a drawing, with clear instructions, how to fix a set of teeth and eyes in a human skull, and how to work the same by electricity?—LES DENTS.

[46381.]—**Three-Legged Dead-beat Escapement.**—Will "Alfojoe," or some other kind correspondent, describe (with sketch) the three-legged dead-beat escapement?—PROGRESS.

[46382.]—**Flat Feet.**—To DR. EDMUNDS.—Can anything be done to improve flat feet in a child under four years of age? A few remarks, in Dr. Edmunds' lucid style, on the treatment generally—as far as the parents are concerned, of flat feet, bow legs, knock-knees, weak ankles, would, I think, be useful.—H.

[46383.]—**H.P. of Locomotives.**—Could not some of your correspondents give us particulars of the indicated h.p. and consumption for power of locomotives? Now that the subject is being taken up, information as to the performance of engines in actual service for goods and mineral traffic would be interesting to your readers.—CONOD.

[46384.]—**Balance Springs.**—Would some of "ours" kindly say the easiest and quickest way to coil or recoil balance-springs? and oblige—GUYOT.

[46385.]—**American Birch Stain.**—Will anyone tell me what cabinet-makers stain wood with to imitate American birch?—JOINER.

[46386.]—**Cold-Air Engine.**—To "SUNLIGHT."—Could you tell me whether I should be infringing on anyone's patent by making a cold-air engine, and if not, will you kindly help me as to what kind of machine will be best, and size that will be required to supply a cylinder of 3in. bore? And will you also oblige by giving me the advantages of hot air over cold air?—SUMMIT OF ENGLAND.

[46387.]—**Boiler.**—I want a boiler for engine of following dimensions:—Length of stroke 2¾in.; bore of cylinder, 1¼in. Could "Sunlight" or any reader give me size and form for burning coal?—SAM WELLER.

[46388.]—**Plaster Blocks.**—I want to make some plaster of Paris blocks, 5in. × 4in. × 6in. thick. Could any friend give me any information how to make the plaster set quick and very hard? I find that, after being dried in the foundry-stove, and then used in the sand, they get soft. If they are dried quick, they crack. Can there be anything done to prevent this?—LADLE.

[46389.]—**Finding Moon's Position.**—The plan which I explained appears to give the position of the moon with regard to the earth with as sufficient accuracy as I require: at any rate, it agrees with the two examples given by "F.R.A.S.," and with other observations made since. I have placed over a circular map of Northern Hemisphere, a piece of tracing-paper, with hours ruled from 1 to 24h. exactly, as on the map underneath. On Feb. 17th the moon is new at 14h. 49m.; now if the tracing-paper is turned until 14h. 49m. is on the meridian of Greenwich, the sun is 9h. 11m. west of this meridian. On the 17th the hour of the Transit of Aries is 2h. 10m.; and counting eastward from this point, a longitude equal to the sun's right ascension, which is 22h. 3m., it gives the sun's position 137 west longitude. Counting the longitude equal to the moon's right ascension, which is 21h. 59m. from the same point (Transit of Aries), 2h. 10m., it gives the position of the moon in the same longitude. Finding the declination of each luminary, the sun is 11° 54s., the moon, 6° 59′. For the longitude of the moon is equal to its right ascension, and its latitude to its declination. When the moon is in conjunction, she is over the centre of New Guinea. On the 18th the moon is on the equator at 21h.; right ascension, 23h. 10m.; transit of the First Point of Aries, 2h. 6m., which would give her position when on equator, about 65° east longitude. This method is simple enough, if it may be considered accurate, but am quite open to correction on the point. What I wished to know with regard to solar eclipses was, the average length of time occupied from the beginning to end of eclipse. Thus the eclipse on May 16th begins generally at 16h. 52m., and ends at 22h. 20m. Will "F.R.A.S." kindly tell me the longest and shortest time an eclipse can take. I ought to have said, I suppose "penumbra" and not "disc" in my last question. With regard to the lines showing the extension of eclipse on the diagrams in *N. A.*, I should have thought they could have been explained, so as to give some idea on what principle they are drawn, without mathematics. My object is certainly not to make calculations, but to understand why they take the shape they do.—W. L. O.

[46390.]—**Turning Cotton Calender Rollers.**—The rollers of calender are 5ft. long, and 2ft. 6in. dia.; and as I run a deal of heavy cloth from 36in. to 45in. wide, the rollers wear down in the middle where the cloth is run. I want to know the best way to turn, or rather scrape, the ends of rollers down (in their places, of course) to make them comparatively true and smooth; great accuracy is not required. What kind of tools should be used? What speed should the calender be run at while scraping? And should the rollers be kept slightly wet or dry during the operation?—G. H.

[46391.]—**Anæsthetics.**—Can anyone inform me how ethydene-bichloride is made? At present it costs about 6s. 6d. an ounce; and considering its great value as a safe and efficient anæsthetic not interfering with the action of the heart, it is a great pity that it is not cheaper, so as to be universal.—SURGEON.

[46392.]—**Froth.**—How is it that when a mixture of soap and water is agitated, a froth is formed on the surface? Is it due to absorption of air, or to chemical reaction? Also, how does calcium carbonate, and other mineral salts found in spring-water, hinder this froth from being formed?—SOAP.

[46393.]—**Soap.**—What would be the action of potash, or any other alkali, upon a solution of soap—stearate of soda, for instance? Also, has soap, or its solution in water, any action on lead, and if so, what?—SOAP.

[46394.]—**Timing French or Other Pendulums.**—I find in Britten's book, pp. 159: "Timing French Pendulums. — Escape-wheels of French pendulus [what is "pendulus"?] make two revolutions a minute, or four vibrations to each tooth. They may be quickly brought to time by counting if the beats of pendulum per minute equals four times the number of teeth in escape-wheel." The first part of this I don't understand—viz., "French pendulus make two revolutions a minute, or four vibrations to one tooth." I am trying to "time" a French timepiece. I find 32 teeth in escape-wheel; therefore, according to latter part of above rule, I say 32

4

—

128 = motions of pendulum per minute.

But I find the French pendulum in question moves about 160 times to one minute of regulator, and yet this French timepiece seems to keep time. Will someone who understands pendulums and numbers, answer without fractions or back numbers?—GUYOT.

[46395.]—**G.W.R. Engines.**—Can any correspondent give dimensions, or, if possible, sketch, of one of the G.W.R. (late B.E.R.) four-coupled bogie saddle-tank locos., 2042 class?—STENTOR.

[46396.]—**To "Aldebaran."**—I have been informed that in a terrestrial telescope there are more lenses than in an astronomical one. If this telescope were used for astronomy, would the extra lenses lessen power and definition of instrument? If so, what lenses should I have to remove to remedy this deficiency?—WYKEHAMIST.

[46397.]—**Slide-valve.**—To "SUNLIGHT."—Would you kindly inform me in what way the double slide-valves seen on beam-engines work, so as to cut off steam at various fractions of the stroke, as required by engineers? A sketch would greatly oblige—WYKEHAMIST.

[46398.]—**L. & N.W.R. Engines.**—Would any reader of the "E. M." kindly supply me with the names and classes of the following engines?—955, 221, 513, 488, 846, and also where they are stationed.—T. R. H.

[46399.]—**Small Quantity Battery.**—To MR. LANCASTER.—Will you kindly inform me whether I can have a small battery (without liquid) that will fuse fine wire? I have made a chloride of silver one, but that will not do it. I know that a small bichromate would do this; but I want one without the necessity of withdrawing the zinc when not in use, and that would stand being turned upside down, and be permanent for, say, a few days. Size, about 4in. square, or less.—CARBON.

[46400.] — **Winter's Plate Electrical Machine.**—1. Having succeeded in making a stout 15in. circular plate of glass, with a 6-8in. hole in the centre, I should much like to construct a Winter's plate machine; but never having seen one, only a diagram in a small catalogue, though I have made cylinder machines and a small 8in. plate (ordinary), and know how to insulate the parts—make the woodwork, make framework, what I want to know is, how to make the ring for condenser, and the best material to make it of, and size? The rubbers, how to make, and what of, for the best—for a Winter's plate machine? Also, how to make a diamond spotted jar? I have made lots of ordinary Leyden jars; I have also succeeded in making small coils. 2. Also, I thank the Editor for diagrams, and inserting Mr. Andrew's coil, p. 15, last No.; and thank Mr. Andrews for his explicit manner. Please, why is the coil divided into three parts for the secondary current? Is it better so than wound from end to end without divisions, and why? Would Mr. Andrews give us a diagram of a good winder, as 1lb. of 36 wire would be about one mile long, and would require some winding?—MUDDLED INQUIRER.

[46401.]—**Arago's "Popular Astronomy."**—In the translation of this work, published in 1858, by Prof. Grant and Admiral Smyth, there appear three star-maps. In these, the following stars are assigned the magnitudes appended:—Gemini: β, δ, ϵ, θ, μ, ν, 2. Perseus: ϵ, γ, 2. Draco: γ, β, 3. Cassiopeia: ζ, 2. Ophiuchus: α, 1. Cygnus: α, 1; γ, ϵ, 3; η, 4. Ursa Minor: β, 3. Pegasus; γ, 2. Auriga, ι, 4. Taurus, ζ, 4. Can anyone tell me the authorities? Mistakes there are in the maps. Castor and Pollux are reversed; the same stars have different magnitudes in different maps, &c. Also, whence came the constellation, "Duo Asini"?—S. M. B. G.

[46402.]—**Cement.**—Is there any cement which will stand the heat of boiling tea? I ask, because I wish to repair certain very old and very fine china cups and saucers, which have been broken, and which (as favourites) we are loth to turn into mere ornaments.—HOUSEKEEPER.

[46403.]—**Cottage-Building.**—Will some reader give me some hints as to building a cottage of five rooms, all on a ground-floor? Brick, and faced up with yellow bricks; rooms about 14ft. square, 10ft. high; rubble-fronted, with bay windows in front. The probable quantity of materials and cost? Have plenty of spare time on hand; could do most of the woodwork myself, and general superintendence.—EMPLOYMENT.

[46404.]—**Medical Battery.**—Will any kind reader tell me how to construct a medical battery in the cheapest form?—IRON MOULDER.

[46405.]—**Stains on Dry-Plate Negatives.**—Will Mr. Lancaster, or some other reader, tell me how I am to remove yellow stains from dry-plate negatives? I use the pyro developer. Also, how can I bring some negatives back to their original printing quality? They were intensified with mercury, and have gone quite yellow all over.—J. L.

[46406.]—**Rainband Spectroscope.**—Can Mr. J. R. Capron, or any other reader, give description of the spectroscope used for detecting rainbands?—R. B.

[46407.]—**Tricycle.**—To J. A. JEFFREY.—In "ours" of the 23rd July, 1880, I notice an illustration of a tricycle, designed by Mr J. A. Jeffrey (letter 17507). As I am desirous of purchasing one of the kind, I shall feel exceedingly obliged if the maker will communicate with me, and give further details, or a catalogue of tricycles which have been manufactured of the best and latest approved descriptions. I have seen several tricycles, such as "Flying Scud," &c.; but I approve the one illustrated in your journal of the above date.—JEHANGIR HORUMSJIE, 31, Cawasjee Patell-street, Fort Bombay, Feb. 16th, 1882.

[46408.]—**Copper Salts.**—In "Workshop Receipts" I read: "Zinc, as soon as immersed in a solution of sulphate of copper, decomposes the salt, and is covered with a muddy precipitate of copper. It is neccessary to give the zinc a thick coating of copper in the bath of double salts before submitting it to the action of the sulphate of copper." Will someone be good enough to inform me, in plain terms, how this "bath of double salts" is to be made and used? I have read over all that I could find in "Workshop Receipts," and in several works of chemistry bearing on this subject; but it is my misfortune rather than my fault that I am quite at a loss to know how to perform this apparently easy operation.—D'EVLYN.

[46409.]—**Sulphuric Acid.**—Will "Analyst," Barker Cooke, "Chemistiana," or some other kind brother-reader please inform me how to obtain the percentage of $H_2 SO_4$ in ordinary sulphuric acid from the sp. gr., without having to resort to a sulphuric-acid table? Some time ago a fellow-workman told me that Dr. Ure used a factor which, when multiplied by the sp. gr. gave the percentage of $H_2 SO_4$ direct.—CHAMBERMAN.

[46410.]—**Velocity of Discharge from Pipe.**—Would anyone tell me what would be the velocity and discharge of a 2in. and a 3in. pipe respectively, of a mile in length, with a fall of 500′?—E.

[46411.]—**Bad Eyelids.**—To DR. EDMUNDS.—I am very much troubled with pustules or pimples upon the eyeballs (as described on p. 512, Vol. XXXIV.), and every time they come, they leave little scars. I have now suffered with them for more than nine years (since I was 14 years of age); vision is damaged of both eyes, especially the right one. I have tried several medical men in the neighbourhood, and have used a great quantity of lotions and ointment—but to very little purpose. Last summer my eye was seriously affected with one of the pimples on the edge of the pupil, which left a scar, similar to the description given in answer to "Ten Years Reader," query 19706. The colour of the white of my eyes is not what it used to be; it is darker, especially the corners—it might be with using the lotion. Sometimes they are bloodshot, and feel stiff or dry when reading or doing anything with artificial light. I am now using an ointment, called the "Poor Man's Friend," which was recommended to me by a lady, by applying a little on the eyes when closed every night. I may also state that I enjoy general good health.—J. W., North Wales.

[46412.]—**Pendulum Spring.**—Will "Nicholls" tell me how to get old spring out of pendulum collet? Also, how to cut off inner end to admit pendulum collet? Also, how to tell the proper strength and size, and to get true in the flat after it is pinned in the collet?—PIVOTER.

[46413.]—**Bamboo Whistle.**—Could anyone advise how I should set out the sound-holes for a large whistle of bamboo, similar in design to the tin whistles sold at the toyshop, and about the size and pitch of a full-size flute (Lower F, I think, is the name of the pitch)? I want the dimensions of the holes, and distances apart from centres of each; also the diameter and bore of tube.—HARMONICUS.

[46414.]—**Electric Engine.**—To MR. LANCASTER.—I have long been anxious to make one to drive a tricycle which I see you propose doing. I shall be glad of any particulars you can give me to make such a motor. Can you, or any other reader, give me information as to carbonic acid gas engines? I mean an engine to work by carbonic acid gas, with a generator instead of a steam-boiler.—E. A., Liverpool.

[46415.]—**North London Railway.**—Can any reader oblige me with a sketch of one of the bogie-tank engines, inside cylinders? and also of one of the outside cylinder engines of the N.L.R., with details of dimensions, &c.? What is their power?—E. E. R. TRATMAN.

[46416.]—**Precipitating Alcoholic Solutions.**—Will some contributor of "ours" tell me how to precipitate the resinoids, &c., from their alcoholic solutions? I made a tincture, 3oz. of bark powdered to the pint S.V.R., put 1oz. of this into a winebottle, and added one pint water; it has thrown down a precipitate, but will not clear itself.—ONE IN A FIX.

[46417.]—**Instantaneous Photography.**—What are the theoretical laws that rule the successful taking (by photography) of an object in motion? I presume that the shutter of the lens must open and close in a time during which the subject in motion to be photographed has not appreciably moved. Now I have read of an express train in motion being photographed as if it was still. Reckoning its speed at 50 miles an hour, this gives the train a speed of 73ft. per second. It is obvious that even a 10th of a second's exposure would produce a blurr, and if only 1-73rd second's exposure was given, would not the movement of the train through the foot of space be sufficient to make the impression indistinct? This is the point of my query: can any shutter worked by mechanical appliances by means of the hands, be opened and closed in so short a period as even 1-50th of a second? To me it seems impossible; and I altogether doubt the statement that exposures of not more than 1-500th of a second have been taken.—IN THE DARK.

[46418.]—**Photography.**—Will some kind reader please give me a detailed account of 1. The kind of gelatine to use for making up a solution with bichromate of potash for producing a sensitive film on a sheet of zinc for the purpose of printing on under a negative after the style of collotypy or Woodbury type? 2. The quantities of bichromate potash and gelatine, and mode of preparation, and evenly covering the plate with the mixture? 3. The best plan to follow, after having exposed the plate under a negative, to obtain a suitable picture to print from in ink after the manner of ordinary printing? 4. Is it necessary to work this in the dark, as I am—IN WANT OF LIGHT.

[46419.]—**Telescope.**—To "ALDEBARAN."—I have a 2¼in. Ross; it is a marine glass. How am I to make it into an astronomical one? Cost £8 when new, and so ought to be a good one.—WYKEHAMIST.

[46420.]—**Cupola.**—Will "Sunlight," or some other reader kindly send sketch of a cupola furnace for melting 4 or 5cwt. of iron, with list of tools and appliances necessary for working a small foundry?—A CONSTANT SUBSCRIBER.

[46421.]—**Boat-Building.**—I wish to build an iron boat suitable for sea-coasting that one or two could manage. Will any reader please give size for plates and ribs, and could I build it in streaks or plates, or is there any good book on iron boat-building? If so, what price, and where could I obtain it? Please give directions for cutting out plates, and so forth; am a smith by trade.—BLACK VIC.

[46422.]—**Organ.**—To MR. DRESSER.—Encouraged as I have been by your most explicit articles in the "E. M." on "The Organ and How to Make It," from time to time, I have got well on with a small two-stop organ—viz., CC to G, 56 pipes of S.D. and Wald Flute, Ten. C to G, 44 pipes. The twelve bass pipes of S.D. I have placed on a separate soundboard at the back, to save space laterally. Will you be so kind as to favour me with a descriptive sketch of a simple octave coupler to be used in connection with the treble part of S.D. and Wald Flute—viz., Ten. C to G, 44 pipes? The 12 S.D. pipes I do not wish to couple to treble, but to use them as bass to others. I have also room on my treble soundboard for a Piccolo to Ten. C. I may add that my action is as per your instructions, the fan frame.—JARVIS BRASSFACE.

[46423.]—**Gravity Clocks.**—To "CLERKENWELL CLOCKMAKER."—Is it necessary to harden and temper the barrel-arbor of these clocks?—J. R. H.

[46424.]—**Circular Saw.**—Lately, when cutting wood by means of a 6in. circular saw, I found that the wood was cut to a curve, although the guide was accurately placed, and the wood carefully fed up to the saw. On removing saw from spindle, and placing straight-edge across the face of saw, I found it was not flat as it should be, but convex or concave, depending on which side the straight-edge was placed. Will some person practically acquainted with circular saws and the treatment proper for them in such cases as the one described, kindly advise me what to do to make my saw flat again, and keep it so? Perhaps "Jack of All Trades" will help—CIRCULAR SAW.

[46425.]—**Gelatine Emulsion.**—Can any of "ours" inform me how long the above will keep in stoppered bottles after it has been washed, and best way of washing same, and if it will keep best without being washed?—DARK SLIDE.

[46426.]—**Blackleading Scorched Iron.**—I have a steel and black fender, and the bottom plate will not take blacklead. It brushes off and looks smeary. Can you inform me what I can do it to make it take the blacklead? I wrote to the house I had it from, and they said it was what they termed a "scorched plate." The distance is too great to return it, so if anyone could inform me, I should be obliged.—HOUSEKEEPER.

FRIDAY, MARCH 24, 1882.

PHOTOMETRIC STANDARDS AND IMPROVEMENTS IN GAS ILLUMINATION.

THE statements made with regard to the photometric value of many of the electric lights now seeking public favour have undoubtedly done much to stimulate an inquiry into the subject of photometry, a branch of science which has long been in anything but a satisfactory state. So long as the lights to be measured kept within the moderate bounds of twenty, or even fifty candles, little difficulty was experienced in arriving at an approximately accurate estimate of the power of any given lamp; but with the advent of the electric light, and so many systems competing for recognition and support, it becomes almost of the first importance to be able to gauge, with some approach to accuracy, the merits of the rivals, purely from the point of view of illuminating power. Incandescent lamps are stated to be of 15, 20, or even 50 candle-power, and there should not be any very great difficulty in ascertaining how far the statements may be trusted; but when we come to use lights of 2,000 candle-power, and especially one said to be of 150,000 candle-power, now exhibiting at the Crystal Palace, the suspicion arises that the "power" has been assigned in a haphazard fashion, and represents rather what the sponsors consider it ought to be, than what it really is. It is tolerably obvious that the Bunsen, and similar photometers, are practically useless when we have to measure the illuminating power of a light said to be equal to 2,000 candles, and it is not by any means a reflection on the veracity of those who claim 150,000 candles for a certainly wonderfully brilliant arc light, if we venture to say that, for aught we or they know, the light in question may be either 100,000 candles or 200,000, for the simple reason that at present we are without any trustworthy means of measuring lights of such power. The method proposed by Dr. Paget Higgs of estimating the candle power of the arc by the heat radiated, or of taking it as the second power of the work in the circuit, may give an approximately accurate result, but at present there is no evidence to show that it is anything more than arbitrary basis, as far from the real truth as a supposition adopted for the purpose of showing the working out of a theory. As a matter of fact, it is not at all certain that the methods usually adopted for measuring lights so comparatively feeble as a twenty-candle gas-burner are capable of giving more than an approximately accurate result, so that the magnitude of the difficulty can be readily appreciated when we have an arc light nominally of 2,000 candle-power to deal with. Profs Ayrton and Perry have sought to meet the difficulty by comparing the electric light with that of the standard sperm candle after the former has passed through a concave lens, so arranged that the diverging ray has been reduced in intensity to the equivalent of, or to something comparable with the candle. The two shadows are examined through ruby-red, and subsequently through "signal-green" glass, the latter being most favourable to the electric light, but they hesitate to take the mean as the relative illuminating power of the arc compared with the candle. Probably their method is as useful, and gives results as correct, as any other that has been proposed; but in view of the fact that it is not easy to determine with accuracy at all times the illuminating power of a light nominally of, say, 30 candles, it will be understood that when an arc-light is said to be of 2,000 candle power, the statement can be accepted only with a certain amount of reservation. In a paper read before the Society of Arts by Mr. Harold B. Dixon, the Secretary of the Board of Trade Committee appointed to report upon three proposed photometric standards, the author showed that a number of standard sperm candles by different makers gave different results when employed in testing coal-gas which the committee had every reason to believe was perfectly permanent, so far as its illuminating power was concerned. The gas was stored specially for the use of the committee by Mr. G. Livesey, at the South Metropolitan Gas-works, and packets of candles were tried against others by the same maker, as well as against candles from other firms. As evidence of the uselessness of candles as standards, it will be sufficient to mention that while one pair gave the gas an illuminating power of 16, another pair made it 18·5, and this difference, be it noted, on the same day. On another day, the power, as given by two pairs of candles, was 17·1 and 19·5. Similar differences were found by taking the average result given by ten candles from different packets. With one lot the average illuminating power of the gas was estimated as 15, with another at 17·2. Personal equation may have some slight effect in reading off the illuminating power; but the real cause of the difference would appear to have been disclosed by the comparison of some of the candles themselves in a test of twenty minutes, readings being taken every minute. In this trial differences of more than 18 per cent. were found, and within two minutes a variation of more than 12 per cent. It will be remembered that ultimately the committee reported in favour of Mr. A. V. Harcourt's air-gas flame as a photometric standard, because a series of experiments showed that concordant results were always obtained with it. The hydrocarbon used is obtained from purified petroleum, and has a specific gravity approximating to that of pure pentane, but it invariably contains some tetrane and hexane. A series of observations made every minute upon two air-gas flames showed that in no case did they vary more than ·1, while the mean shows a difference of ·01 only. It appears, then, that a standard light of a really trustworthy character is available for measuring the illuminating power of lamps of comparatively small candle-power, and it remains to be seen in what way it can be utilised to measure the powerful arc lamps now so familiar. It will be remembered that besides the powerful compound gas-burners recently made by Bray, Sugg, and not least by Wigham, an important innovation has been introduced in the shape of the regenerative gas-burners devised by Dr. C. W. Siemens in this country, and also by his brother Herr F. Siemens, of Dresden (vide pp. 532,555, Vol. XXXII., and p. 372, Vol. XXXIII.). In these burners not only is the air-supply heated, but so also is the gas, and from the statements of Mr. A. V. Harcourt, in a paper read recently before the Society of Arts, we learn that with a lamp of Herr F. Siemens' pattern the extraordinary light of 5·8 candles per cubic foot of gas has been obtained. That result was found by Mr Keates using a smaller burner than the usual size, and of a different form, but with ordinary specimens of the regenerative burner Mr. Keates obtains 5½ candles per cubic foot of gas. What that means will be understood when it is stated that a London argand—the standard testing burner—gives only 3·2 candles per cubic foot of 16 candle-gas, while common No. 3 union-jet gives only 1·3 candle per cubic foot per hour. Mr. Harcourt's experiments with the Siemens regenerative burner did not yield results so high as those obtained by Mr. Keates, owing, it appears, to the lamp being one specially made for a different quality of gas; but as compared with a 100-candle argand of Sugg's make, which gave 3·64 candles per cubic foot, the Siemens gave 4·8 candles, so that there is obviously a very high economy due to the regenerative principle, which amply covers the extra cost of the lamps. The application of the regenerative principle, as it is called, is not altogether novel, for it appears that so long ago as 1843 Faraday used a burner in which the products of combustion were drawn down between an inner and an outer glass chimney; and later, Dr. Frankland used a somewhat similar device with the avowed purpose of improving the light. Whether the Siemens regenerative burners will come into use for street-lighting purposes remains to be seen—probably they will be voted too complicated; but as coal-gas, for its complete combustion, requires about five times its own volume of air, and its illuminating power depends on the heat of the flame, it is obvious that an advantage in light-giving power must be obtained by heating the air supply as hot as possible; and if that can be done in a simple manner, great economy can be effected in gas-lighting. With gas-lamps of a known power of, say, 100 candles—some existing lamps are of 180 candles—we have a possible standard by which to compare the electric arc, and those who have seen the two lights will have little difficulty in deciding which arrangement would most effectually illuminate a large room or a hall—20 Siemens' 100-candle regenerative gas-lamps, or one so-called 2000-candle arc light; but in that case, the gas-lamps, by being distributed, would have an unfair advantage, for an arc light, no matter of what power, can be distributed only by the aid of reflectors. Therein lies the vantage of gas as compared with electricity; and as the incandescent systems can at present scarcely compete with the improved gas-lights on the score of cost (though on this point a different opinion is expressed by Mr. Swan, whose remarks will be found on p. 29, last number), it would seem that the latter are likely to run the "new light" a very close race; still, as the possibilities of improvement are greatly in favour of the electric light, it will in all probability beat its rival in a tolerably near future.

REVIEWS.

Elementary Lessons in Electricity and Magnetism. By SILVANUS P. THOMPSON, B.A., D.Sc. London: Macmillan and Co.

THIS work appears most opportunely at a time when many persons are asking for information on electrical subjects, and though it is obviously intended for students, the general public will be able to turn to its pages with the certainty of obtaining trustworthy information. The author says that his work is but the introduction to a very widely-extended science, and refers the student who desires more information to the works of Faraday, Mascart, Maxwell, Thomson, and Wiedemann; but, although these are "elementary lessons," we may fairly consider that the reader or student who makes himself familiar with all that is to be found within the covers of this book will understand a great deal more of the real nature of electricity than many of those who have learned the subject as taught at some of the schools. The theory put forward in these pages, as would be expected by those who know something of the author's work, is that electricity, whatever its real nature may be, is one, not two; that it is not matter, nor is it energy; but it resembles both in one respect—it can neither be created nor destroyed. The doctrine of the conservation of electricity, like that of the conservation of energy, teaches that we can alter the distribution of electricity, by causing more to appear at one place and less at another; but we can neither destroy nor create it, although we may appear to do so, when we turn a plate-machine, or immerse plates of different metals in certain liquids. Frictional and current electricity and magnetism are so intimately connected one with another, that it is next to impossible to obtain an accurate knowledge of one branch without knowing something of the two others; so Professor Thompson has devoted the first three chapters to a simple exposition of the prominent facts as seen in experiments, reserving a consideration of the points of connection until in later chapters he introduces so much of theory as is consistent with the character of the book. The reader who takes up the work with a determination to understand it, will find that he requires only the merest smattering of algebra and geometry, while the numerous illustrations will materially assist him in comprehending the text. The unit terms employed throughout are the volt, ohm, and weber, but an appendix mentions the changes proposed at the Congress held in Paris. A number of problems and exercises on each chapter are printed at the end, and complete the work as a textbook for schools and science classes.

The Watchmaker's Handbook. By CLAUDIUS SAUNIER. Translated, revised, and considerably augmented by JULIEN TRIPPLIN and EDWARD RIGG, M.A. London: J. Tripplin; New York: Keller and Co.

THIS handbook is a combination of two works by M. Saunier, translated and edited by M. Tripplin, a watchmaker of Besançon, and Mr. E. Rigg, of the Royal Mint, a gentleman who is an acknowledged authority on the subject in this country. M. Saunier's works are recognised and extensively used in the technical schools of the Continent, and a glance through the pages of the English translation, or rather edition, will suffice to show that it is a work admirably adapted to the wants of "improvers" and amateurs, and especially so in the case of those who are entering for the technological examinations. It is, in fact, a complete manual of practical watchmaking, and contains besides many hints which will be found useful by mechanics in many branches of the different trades. The work is divided into six parts, which treat respectively of arithmetic, geometry, and measurement; of the materials employed in the art, their preparation, treatment, and application; of the health of the workers, and their habits in the shop; of tools and appliances; of repairing and examining watches; and, as a conclusion, about 100 pages are devoted to practical receipts and workshop hints, many of which will be found of considerable value not only by tyros, but also, we suspect, by numbers of watchmakers scattered over the country. It is, in fact, no undeserved praise of this book to say that it ought to form part of the stock-in-trade of every watchmaker, no matter how skilful he may be; for if he can improve on its teaching, there are students willing to learn, and space for his remarks. The illustrations are mainly in the shape of plates, containing about 200 separate figures, and are placed at the end of the volume; but scattered through the text are a number of woodblocks of special interest. The editors have done their work excellently, and have not lost sight of what is too often considered a mere minor matter; for, besides providing a table of contents and an index, they have inserted cross references in a very thorough manner, so that the workman will experience little, if any, difficulty in referring to any point on which he may require information. We need not say that is a very important consideration in a "handbook," and this book is, we have no hesitation in saying, a real vade-mecum for the watchmaker and jobber. It should be distinctly understood that it is essentially a practical manual, and is the companion volume or complement of Saunier's "Treatise on Modern Horology."

Useful Information on Electric Lighting. By KILLINGWORTH HEDGES. London: E. and F. N. Spon.

INFORMATION about electric lighting is now sought by so many of the public that, although this is the third edition of Mr. Hedges' manual, we can appropriately devote a few lines to it, especially as it has been revised and enlarged. Many persons who happen to be acquainted with the expenses of installing the electric light, will scarcely go with Mr. Hedges in asserting that "it surpasses by far in economy and beauty all other known illuminants," especially as in another part of his book he thus speaks of undoubtedly the most beautiful system:—"If lighting by incandescence becomes the practical success its advocates believe it will, it is still doubtful whether it will ever be sufficiently economical to warrant its superseding gas in all cases." Here we have obviously a difference of opinion; but there are many hints in Mr. Hedges' book which intending users of the electric light will do well to read before investing in plant. By the way, why does he head some of his pages "Division of the Electric Light," and puzzle his readers with division of the current and division of the light? In that and some other points the book requires another revision; but nevertheless it is a useful guide to those who understand nothing about the subject and have no time to acquire a knowledge of even the rudiments. In a section of "cautions" Mr. Hedges says that if alternating currents be used, or a machine of very high electromotive force, as in the Brush system, it is dangerous to touch any part of the gear at all when in action, especially if standing on metal or on the damp ground. If that is the case, how are the attendants to know when any bearings become hot? An explanation of terms is given at the end of the book, and there we find that electromotive force means the *force* which develops electric tension or potential. There are some other statements of the same vague, not to say incorrect, character.

We have also received *The Watch and Clockmaker's Handbook*, by F. J. BRITTEN (Kent and Co.), a useful work containing much information for the trade, and a number of illustrations, many of them referring to "novelties," so far as the average jobber is concerned. A table of differences of time between Greenwich and other places would be useful if it were trustworthy; but according to this book Ramsgate is 5m. 55s. slow compared with Greenwich, while Margate is 5m. 55s. fast; further, Portsmouth and Plymouth, are both put down as 16m. 16s. slow, and yet this is the "fourth edition."——*The Miners' Manual*, by L. A. ATHERLEY-JONES, B.A. (Cassells), is a legal handybook for miners, whether employers or employed, and is dedicated to the Durham Miners' Association. It is a summary of the laws relating to mines, employers and employed, conspiracy, trade-unions, and royalties, and as it is provided with a good index, will be a real miner's "manual" of the law as it affects his calling.——*Geometrical Exercises for Beginners*, by SAMUEL CONSTABLE (Macmillan and Co.), is a little book which will be helpful to students who are unable to obtain at all times the assistance of a tutor.——*Treatise on the Combined Circular, Spiral, Multi-Index Slide-Rule*, by THOS. DIXON (the Author, Buttershaw, near Bradford, Yorks), is a revised edition of a little book that is found useful by mechanics in all branches, and by all engaged in making calculations. It contains a number of examples and copious tables for use with an instrument which is equivalent to Gunter's scale nearly 50ft. long.——*The Philosophy of Advertising*, by HENRY SELL (the Author, Bolt-court, E.C.), is a work that contains many useful hints to advertisers, and an extended list of the various media for their announcements.——*A Treatise on the Theory of Determinants*, by THOS. MUIR, M.A. (Macmillan), is a full exposition of the theory in a form suitable for students, and is probably the only book which deals separately with the branch of mathematics known as determinants, in a compact and handy form.——*Slide-Valve Gears*, by HUGO BILGRAM (Philadelphia: Claxton, Remsen, and Haffelfinger) is a book we noticed when it first appeared; but Mr. Bilgram sends us another copy, as he thinks that questions will arise as to the relative value of his system as compared with those of Zeuner and Reuleaux. Mr. Bilgram offers to reply to any inquiries relating to his method, and as his book is published at one dollar, those interested in slide-valves and their setting will no doubt add it to their libraries. We gave an article from Mr. Bilgram's pen on p. 537, No. 881, which will give a general idea of his method.——*The Tricyclist's Vade-Mecum* (Chas. Cordingley, Hammersmith), is one of those publications which describe the various machines in the market much in the same way as they are described by their makers. As a guide to the choice of a machine it is simply a puzzle, and the generally good advice tendered as to diet, &c., is rendered ludicrous by the statement that oatmeal water is the best of all thirst-quenchers, and has the advantage of supplying *silica* to the bones.

We have also to acknowledge *Railways and Locomotives*, by J. W. BARRY, M.I.C.E., and F. J. BRAMWELL, M.I.C.E. (Longmans); *Handbook of the Polariscope*, adapted from the German of H. Landolt, by D. C. ROBB and V. H. VELEY (Macmillans); and *Vibratory Motion and Sound*, by J. D. EVERETT, M.A. (Longmans).

ON THE IRRATIONALITY OF THE SPECTRUM IN ITS RELATION TO THE ACHROMATISM OF OPTICAL INSTRUMENTS.—VII.

By "ORDERIC VITAL."

(*Concluded from page 584, Vol. XXXIV.*)

BREWSTER gives the approximate position of the mean ray, in the spectra of five different media, the first having the most action on green light, and the fifth the least.

1. With sulphuric acid, the mean ray is about the middle of the green space.
2. With hydrochloric acid, the mean ray is about half-way between the middle of the green, and the junction of the green and blue.
3. With crown glass, it is at the junction of the green and blue.
4. With flint glass, it is slightly advanced on the blue space.
5. With oil of cassia, it is considerably advanced on the blue space.

I now pass on to consider what conclusions may be drawn from the preceding investigations, respecting the properties of glass which is suitable for optical purposes.

And, in the first place, it is obvious that if the secondary spectrum can be eliminated, it must be accomplished by altering the composition of crown glass For a reference to the diagram of spectra will show, that there is a greater discrepancy in the position of the colour, lines for crown glass than for flint glass, and if it is possible by any means to produce a crown glass, which has less action on the green and red portion, the secondary colour can be practically neutralised.

But if this cannot be accomplished, the minimum of chromatic aberration must be obtained, by properly combining the two species of glass. For it will be evident from the diagram, that there is considerable difference in the amount of dispersed colour, produced by crown and flint prisms. It was shown that the greater the difference in dispersive power, the greater is the amount of outstanding colour; so that the first general rule is:—

1. In forming an achromatic combination, crown and flint glass should be used, which have the least possible difference in their dispersive powers.

Thus it would seem that in Fraunhofer's list—crown glass, No. M, and flint glass No. 3, whose dispersive powers are as 8 : 11; and in Chance's list, soft crown and light flint, whose dispersive powers are as 14 : 19, form the most suitable media for combination.

Hence, when two lenses are achromatised (taking δ as the value of the quotient obtained by dividing the crown focal length by that of the flint) such qualities of glass should be used as will permit the value of δ to be about 0·7, or preferably greater; but certainly not very much less.

2. The first rule involves another one—viz., this—if the difference in dispersive power is a minimum, evidently we must have a flint of low dispersion and a crown of high dispersion.

But flint glass of a low dispersive power has a low specific gravity, and, I believe, it has been found easier to manufacture large homogeneous discs of such glass, than of the denser qualities. Hence it would seem advantageous, both theoretically and practically, to use light flint glass in an achromatic lens.

In support of this argument, Brewster quotes the example of the optician Tully, who deservedly obtained a high reputation for the excellent qualities of his object-glasses. His flint lenses varied in specific gravity from 3·192 to 3·466.[*]

There is another matter which is worthy of consideration—viz., the adjustment of the four curves in an achromatic lens.

Two conditions, though not absolutely essential, should, if possible, be fulfilled:—

(α) Chromatic correction is best obtained when the interior surfaces are in contact.

(β) For ease and simplicity of workmanship it is desirable that the crown lens should be equi-convex.

Two other conditions are absolutely essential:

(γ) The curves must satisfy certain given focal lengths.

(δ) They must be so arranged as to destroy the spherical aberration.

The two latter conditions can always be satisfied; generally (α) can be combined with them, but all the four bring the problem into very limited compass.

If we have a crown and flint combination, differing much in dispersive power, a short-focus crown lens, having deep curves, must be used with a long-focus flint, having shallow curves, and conditions α, γ, and δ require the object-glass to be of the Herschel form—a double convex, flatter curve in front, with a concavo-convex flint lens.

It would seem that this form is better adapted for correcting the secondary spectrum, than a double convex with deeper curve in front, united to a double concave. For by reducing the convexity of the anterior surface, we contract the red and green part, and oppose the secondary by a tertiary spectrum; but as the great difference in dispersive power giver more colour uncombined, there is, perhaps, very little difference to be discerned in the action of the two distinct constructions.

But by reducing the dispersion of the flint, the crown-curves approach to equality, and the second lens may be made double concave. When the focus of the crown is to that of the flint as 3 : 4, or the value of δ is 0·75, the front lens may be equi-convex, and the two interior curves may be made equal and opposite.

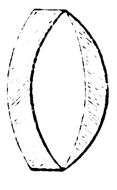
In adjusting the forms of two lenses, to destroy spherical error, the correction should be made with such curves as give the least possible aberration for each lens (due regard being paid to the other conditions); a slight discrepancy between the theoretical and practical curves will then introduce no appreciable error. Now, although this principle cannot be rigidly adhered to in computing the curves of an object-glass, it is always advisable to have as little error as possible for the flint lens to correct. The best form of convex lens has the deeper curve outside; but this is not applicable, since it would cause the inner curves to be very unequal. An equi-convex lens, though causing rather more spherical error, is much better suited for satisfying the condition of interior coincidence.

The alteration in the inclination of the crown prism in Exps. 66, 67, and 68, would seem to indicate that it is possible to neutralise, or even over-correct, the secondary colour, by using a reversed meniscus crown lens, combined with a concavo-convex or bi-convex flint lens. Probably achromatism might be secured by making the first lens plano-convex; but there still remains the question of correction of spherical error; and I think this could hardly be accomplished in such a combination.

It is the common practice to place the crown lens in front of the flint; but, in some kinds of object-glasses, it might prove an advantage to place a convexo-concave of flint in front of a bi-convex or perhaps meniscus crown lens. Such a combination would most likely answer best for camera-lenses or for opera-glass objectives, for the rays on the front lens should be converging rather than parallel.

With regard to an achromatic combination, consisting of two lenses of the same species of glass, Brewster gives a diagram similar to Fig. 9: a convexo-concave lens is placed in front of a reversed meniscus lens. Although each has one concave surface, that of the first is much the deeper, making it a lens of negative focus; while the second one has its focus positive. I doubt whether such a combination could be used as an object-glass, for it does not seem possible to correct the spherical error, which must be considerable; and the wide interior space, arising from the curves being both concave, is another great objection. Brewster does not give any rules for finding the proper ratio of curves; and, indeed, it scarcely seems likely that they can be deduced otherwise than by experiment.

FIG. 9



At this point I must, for the present at least, conclude this series of articles. It has been my endeavour to give a somewhat detailed account of Brewster's researches on the dispersion of light, and I have added such remarks as my own studies have enabled me to make. This applies especially to the first portion devoted to the explanation of various kinds of spectra. Possibly errors may have crept in here and there, and if any such should meet the eye of the reader, I trust he will make a note of them. Brewster's theories may not be accepted by all: even Dr. Wollaston could not agree with the conclusions regarding the alterations in the spectrum by varying the refracting prismatic angle. But I think it is pretty evident that theory and practice agree as to the formation of the tertiary spectrum, which conclusively demonstrates that such an alteration does take place. Perhaps the fact that two lenses of the same glass may be achromatic may lead to some useful result—with eye-lenses and micro-objectives, if not with telescope object-glasses.

Among the readers of this journal there are, I know, many interested in practical optics; to all such as have not access to Brewster's book I trust the foregoing summary of his investigations may prove of some service.

---

[*] Probably the lighter quality was the most used, if we may judge from the table of his curves given by Brewster in the "Edinburgh Encyclopædia," and published in the Correspondence column of this journal.

STEAM AND THE STEAM-ENGINE.—CURVES OF EFFICIENCY.

On p. 197, last volume, we gave a short account of the views of Prof. R. H. Thurston on the ratio of expansion at maximum efficiency, in which he showed that the actual working engine, in all that affects that ratio, is vastly different to the hypothetical or theoretical engine. Prof. Thurston has determined what is the best ratio of expansion experimentally for several standard types of American engines, and in a paper recently read before the New York Academy of Sciences, he has described a method of charting curves of efficiency which will be found worthy of notice by the student of steam-engines. In spite of all that has been said and written on the subject, the question of the steam-jacket cannot be said to be settled, for every now and then we get some figures obtained during a trial of this or that engine, which, as put and utilised for the purposes of argument, appear to show that the steam-jacket is of little if any practical utility. But it is clear that if the jacket fails in its work that is not because the theory is incorrect, but because the conditions—perhaps of construction—are such as to negative any advantage gained by heating the cylinder with steam. Prof. Thurston, who has examined the subject in a thorough manner, concludes that the necessity of following the direction of improvement indicated more than a century ago, viz., the protection of the working fluid from losses of heat by surrounding it with non-conducting surfaces, constitute the most imperative of all demands to-day made upon the mechanical engineer engaged in designing steam-engines. Herein it will be seen that the principle which the steam-jacket is supposed to represent is clearly enunciated, but all that is asserted is just what James Watt stated years ago, that it is essential to keep the cylinder hot to prevent loss of heat from the steam. Prof. Thurston has shown that first friction and then cylinder condensation, due to expansion of a heated fluid in a cylinder constructed of material of high-conducting power modify the methods of expansion and of expenditure of heat so much that the ratio of expansion for maximum efficiency in unjacketed cylinders rarely exceeds $\frac{1}{2}\sqrt{P}$; P being the gauge-pressure. The modifying conditions differently affect various kinds of engines and also individual engines according to pressure and piston speed. It is obvious that in no case can the curve of mean pressures be such as would be obtained in a non-conducting cylinder, for steam must be more or less condensed at the beginning, and must always carry away heat by being re-vaporised at the end of the stroke. The steam-jacket checks the first operation, but accelerates the latter, and with wet steam may possibly do very little indeed to decrease the evil it is designed to prevent. That is especially the case with long-stroke slow-speed engines, as will be readily understood. Thus, to take the actual words of Prof. Thurston:—Consider a steam cylinder unjacketed and worked at some extremely low speed of piston. At the instant before the steam enters either end, that end is exposed to the chilling action of vapors forming on its warm surfaces at the pressure of the exhaust, while the opposite end is just releasing a charge of steam which has been expanded down to some pressure considerably below that of prime steam; the expansion of which charge and the re-evaporation of moisture present, chills the surface of the cylinder on that side of the piston also. Now, the steam entering from the boiler meets the cooled metal surfaces of piston and cylinder head and condenses upon them until they attain boiler temperature, or until the closure of the steam valve checks this operation, and the charge then expands as the piston moves forward with its very slow motion, uncovering, gradually, surfaces which had been cooled by the exhaust on the other side of the piston. The expanding steam, meeting these cold surfaces, surrenders a part of its heat until they are brought fully up to the temperature of the steam, by flow of heat into the interior of the metal, after which time they, in turn, give up heat again to the steam, producing re-evaporation of the water present and giving a pressure exceeding that which would be due the same volume of expanding dry steam. The total effect is evidently determined by the varying temperature of the cylinder walls, the temperature of exhaust and the dryness of the steam supplied. As the piston moves forward, all parts of the cylinder hotter than the mean temperature of exposed surfaces, and all the water present, surrender heat which causes the production of steam and a tendency to increase the normal pressure. The colder surfaces constantly uncovered by the piston absorb heat, produce condensation of steam and tend to reduce pressure below the normal. As the one or the other of these effects predominates, the expansion line rises above or falls below that obtained by adiabatic expansion. These effects are sometimes modified and rendered less observable by the occurrence of leakage—usually and principally through the steam valves—but where, as is frequently the case, the actual expansion line first falls below and then rises above the adiabatic or hyperbolic curve it may be probably safely assumed that leakage does not occur to any important extent.

In the paper, Prof. Thurston goes on to show how by Zeuner's formula the engineer can construct curves of efficiency with a satisfactory degree of accuracy, and the diagrams of curves constructed by him are given in the *Journal* of the Franklin Institute for February; but we have not space to give them, and must content ourselves with reproducing his conclusions. Prof. Thurston also promises another paper on the subject, in which working figures will be given, and we may hope that he will publish his results in book form. He finds: (1) That the work done in a non-conducting cylinder, the fluid expanding adiabatically, varies so little with the proportion of water present that this variation may be neglected by the engineer, and he may assume the performance of work to be such as would come of nearly hyperbolic expansion, while the heat expended may be exactly calculated from the quantity of work, when the latter is known. (2) That, in metal cylinders, the work done at any given point of cut-off is nearly the same as in the non-conducting cylinder, but that the quantity of heat and of steam expended in doing it are increased, and usually very greatly increased, by cylinder-condensation if saturated or wet steam is used, or by other methods of transfer of heat to the exhaust and by consequent waste, if superheated steam or other gaseous working fluid is employed. (3) That the ratio of expansion at maximum efficiency would be practically unchanged by ordinary variations in the proportion of water entrained with the steam, if it were worked in a non-conducting cylinder. (4) That the ratio of expansion at maximum efficiency, when steam or other fluid expands in a metallic cylinder, is more seriously affected by the introduction of water entrained by the steam, and this difference is increased, and usually is made very serious, by the occurrence of cylinder-condensation, or other method of transfer of heat to the exhaust, when a metal cylinder is used. (5) That the quantity of fluid used per stroke in the non-conducting cylinder is in direct and exact proportion with the volume of the cylinder open to the supply-pipe at the instant of closing the expansion-valves, and is measured by $1 / r$, the reciprocal of the ratio of expansion. (6) That the volume of boiler-steam worked per stroke in the metal cylinder is *not* in direct proportion to volume of cylinder open to steam at the point of cut-off, but that it is often very greatly in excess of the latter quantity, and that it becomes greater as the ratio of expansion is increased indefinitely. (7) That the ratio of expansion is not a gauge of the volume of steam demanded from the boiler, and paid for by the proprietor of the apparatus when the metal cylinder is employed; but that the volume of steam used or quantity of heat demanded must very greatly exceed the proportion $1 / r$ in nearly all actual engines. (8) The curve of variation of efficiency above traced, of which the abscissæ measure varying quantities of steam used in a given steam-cylinder, while the ordinates are proportional to the quantities of work done by those amounts of steam, is a curve of entirely different character and form, and often widely different in location, from the curve of adiabatic mean pressures or other curve of mean pressures exhibiting the work done by various quantities of steam expending under given fixed conditions in a non-conducting vessel. (9) That no predetermination of the efficiency of any proposed engine, whether of fluid, of machine, or of capital, can be made unless the true curve of efficiency can be obtained for the assumed case. (10) That the most certain and the most satisfactory solution of any problem of efficiency will be that obtained by first securing the elements of the curve of efficiency from actual engines operated in the manner proposed for the case taken. (11) That, having obtained by experiment upon any engine, the "curve of efficiency," as defined by the writer, the efficiency of fluid, of engine and of capital expended to do a given amount of work, and the quantity of work to be obtained most cheaply from a given engine, may all be obtained for any given set of conditions, and the ratio of expansion, at maximum efficiency, of fluid, of engine and of capital and the ratio of expansion which, with a given plant, gives most work for a dollar of expense of operation, may all be determined with a degree of exactness only limited by the magnitude of the errors of observation.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By John Watson Warman,

Associate of the College of Organists, London.

(*Continued from p.* 607, *Vol. XXXIV.*)

x. INSTANCES of all three of these forms of Regulating Tail are to be met with. The *Button* model is constantly used by *Hill* in cases where the presence of a Detached Buffet, or some other reason, renders it inconvenient to apply the coupler to the *Action* connected with the Keys: his fine Organ in All Saints', Margaret-street, London, may be cited; the precise Treatment is that of the Sloped-Block. Of the Button Regulator with the Under-Sinking instead of the Block, no Example is at present known to the writer: it is his own design, and was called into existence solely or chiefly to accompany his Contracted-Level (2in.) Keys—for which see more fully at 92, *q*—, as used with 4-Manual Instruments. The *Split-Key* Regulator is or was constantly employed by various Builders; *H. Jones*' Instrument in the Wesleyan Chapel, Canterbury, may be mentioned. The *Spring* Form is much less common; a specimen, however, occurs in the Rebuild, by *Gern*, of the Organ in St. James', Addison-road, North, London.

y. *Selection* demands a rather more extended notice:—

The *Button* form is a really good one, and is by no means costly. It is, of course, essential that the proper relative *levels* of the Button and the Block-face (see *u*, ante) be observed in the first adjustment of the parts, and retained—approximately—at all subsequent times. For an additional advantage of the Button Form of Regulator, see what is said directly on as to the *Split-Key* Form. As regards the relative values of the Block and the Under-sunk *Varieties*, it is to be observed that the latter is the simpler, and that it also avoids the possibility of detachment at a glue-joint, eases the working of the Screw-eye, allows such Screw to be shorter, keeps the Keys lighter, and creates more room for the mechanism between the Manuals. This last point, however, is of no advantage (but rather the reverse) except in cases where either the Coupler [between Manuals] is of some *Sticker* form, or the vertical distance apart of such Manuals is *very* contracted. And as all such Sticker forms between Keys are inferior to the Drumstick (see Coupling-Actions), and very contracted Manual Levels are of comparatively rare requirement (see proper Head, at 92, *n*), it becomes obvious that the Block Variety is of the palpably greater utility. On the whole, we may safely lay down that the Under-Sunk treatment should be employed *only* when the Manual Levels are *less* than 2½ inches apart, the Key-tails, at the same time, being *not* Forked; but that the *Block* variety of the Button Form is to be regarded as the *regular* treatment for all ordinarily designed Organs of medium quality in which the Nose of the Action Backfall, Lever, or Square lies in or directly on the Key-tails.

The *Split-Key* form is the cheapest and simplest of the three, and if properly made and adjusted will answer quite satisfactorily, especially if the Key-body be made of some springy kind of wood (see at 87, *x*). But it is imperative that the Tongue be never forced too far from its natural straight position; for if it be, it will very possibly refuse to return tight against the screw on any after slackening of the latter, and so a chattering then result. There exists another disadvantage of the Split-Key treatment which it is well to mention here, and this is that it compels the Cutting for the Off-Clearing (see *u*, ante) to be made in the *Lowermost* of the two Keys (see *v*, ante). It is quite true that this last is considered an actually good point by some Builders, because it permits the Drumsticks to be so *Stoppered up* that they will not drop into said Clearing on the pushing off of the Coupler, and so the Lower Keys can rise without touching the Drumsticks, and all chance of their then causing a rattling of the latter be prevented. But the writer does not agree with this view, for when the weight of the Drumstick is taken off the Key-tail the "balance" of the entire Key (only *slightly* heavier forward, see *h*, next) is obviously interfered with, and the Key rendered more liable to "dance": it is likewise quite true that such Stoppering of the Drumsticks also does away with the *friction* of their contacts in travelling up the Slope; but such friction, though of course better avoided, is never, with the Drumstick Coupler, ficient to be of practical importance. The Cuttings, being made in the Lowermost Manual also gives the advantage of slightly lightening the *longer* and consequently the *heavier* Key; but the amount of decrease is too trifling to be palpable. Cetainly, therefore, the Off-Clearing's having to be in the Lower Manual remains as an objection to the Split-Key Regulator,—because the Drumsticks ought to be allowed to descend into such Clearing, and this may not always be quite convenient in the construction, and will, at any rate, involve the slight friction of the travelling up the Slope. [It is for the foregoing reasons that it is the Upper Key which is directed to receive the Clearing with the *Button* form of Regulator,—see *u*, ante.] On the whole, we may confidently say that the Split-Key Regulator may be freely employed with the *low-priced* Organ, and with all, of whatever quality, where the Key-tail has a Sticker or a Tracker running from it. But the Split-Key form must obviously be never used when such Key-tail is also Forked.

The *Spring* form will have had its *general* value defined by what has been given for the Split-Key. To this, however, it is necessary to add that the Spring allows of a larger extent or variation of Adjustment than does either of the remaining forms; but that, on the other hand, the cost of the Springs is a palpable item. We may therefore lay down that the Spring Regulator should be preferred only in cases where *one* of the two Manuals which it is the object to Couple [together] is liable to *vary* in its Touch-depth, and the *other* of such two is *not* liable to so vary. A suitable Instance of this might be presented in an Organ which possesses a Coupler between its Solo and Swell Manuals, the said Solo having an *Electric* Key-action, and the Swell a *Long Mechanical* one. A similar case might be afforded where the Actions of both of two Unitable Manuals are Mechanical, but one of them Short in length and the other Long. (See on these points in *Pro-Department* Entire Organ.)

[It is to be borne in mind that the foregoing assessments apply solely to the so stated Forms of Regulating Tail as compared with *each other*, and do not at all affect the question of the abstract desirability of such Coupler Regulation as compared with the performing of it at some point along the *Action* itself. Such abstract comparison is obviously simply that of the relative merits of two broad Types of Coupling-Action, and cannot, therefore, be fully gone into except in the *Department* of latter. In the mean time, however, the reader may be again referred to what is said under *S.-S.-Div.* of Design Precise (at Sub. *s*, next), where it will be seen that a Coupler between Manuals possesses some very important advantages, especially as respects the presence of a Detached Buffet, and the provision of a Clear Coupler Great to Pedale.]

---

* All rights reserved.

yy. *Tail-Slot.*—This is the small Mortise or Slot required to be cut through the *Key-Tail* whenever the Sticker leading from another Manual is made to pass through such Tail. The Mortise should always be as wide in the direction of right-to-left as is possible without unduly weakening the Key in which it is made,—the object of such wideness being the prevention of the Sticker foot's ever slipping off the Key-Tail on which it is to rest. In the other direction the Mortise may, of course, be extended as much as desired,—within reasonable limits; and if the Sticker be a Sliding one (see *Depart.* of COUPLING-ACTIONS) such extension —either backwards or forwards—, to a considerable and corresponding distance, becomes an obvious necessity. The Mortise or Slot must always be accurately and cleanly cut, and should, by rights, be slightly larger at its bottom than at its top. See here further at *w*, next.

Instances of the Tail-Slot occur in the Leominster Organ (see at *x*, next), and in that of St. James, London (see *y*, next). It will be noted that in the first of these the treatment was almost compulsory.

As regards *Adoption*, the writer would never recommend or employ the passing of the Sticker through the Key-tail unless under quite exceptional circumstances,—such as those just indicated; and, when so rendered inevitable, care should be taken to avoid the fetter—which fetter will be seen existent in the St. James' Instrument—of the retention of the *foot-wire*. Under even the most favourable Treatment, the Tail-Slot always involves a chance of undue friction, and consequent unbidden sounding; and, in addition, there is the risk of derangement through the Key's warping.

See further in *Department* KEY-ACTION.

yyy. *Tile.*—This will be found given in connection with the Head of *Mortise* and *Boring* (comm. *h*, ante).

z. *Wedge.*—This is the distinctive term applied to the Sloped *Block* or (as the alternative) the *Cutting* which is required to be attached to or made in the Key in all cases where an Action which comes into and out of Contact by a Sliding motion is in connection with such Key. The uses of this Wedge are (1) the securing of the necessary Off-Clearing for the actuator to pass into when the Coupler is not in use, and (2) the provision of a proper [sliding] surface for the Drumstick-head or the Sticker-head to travel smoothly into contact by. The Wedge, both of the Block and the Cutting Forms will therefore have necessarily been (at *u*, ante) described, in connection with the Regulating Tail. A more common employment of the Wedge is or was afforded in its application beneath the Key-tail for the contact of the Sliding-Head Sticker form of Coupler Manuale to Pedale: no additional information will, however, be required in connection with this particular Treatment. As regards the actual *Angle* adopted, it may be considered that such should not be more steep than 40 deg.; and that it needs never ordinarily be less steep than 30 deg. The first named will do very well for all Couplers Manuale to Pedale; the last named will be preferable for all Couplers Manuale to Manuale,—on account of the then larger number of Contacts involving greater Friction. In special cases, an Angle as low as 35 deg. may be used for a Coupler Man. to Ped., and 25 deg. for one of Man. to Man. Under all circumstances, where the Action is that of a Sticker (this will include all Man. to *Ped.* Couplers) the entire Stope and Crown of the Block or of the Cutting must be "Buffed," that is, clothed with a suitable soft substance to prevent noise (see here at 87, *y*); but in all cases where the Action is placed between the Keys no Buffing needs be applied to the latter, for the Head of the *Drumstick*—which has already been stated as the *best* Coupler for such location—can itself more simply and properly receive such Clothing. (See here further at *mm*, next.)

[89, a.] The *Material* of the Wedge (assuming it to be a distinct Block) will be preferably either Pine, Lime, or soft Mahogany.

aa. *Instances* of the Wedge in connection with Couplers Manuale to Pedale were at one time quite common, though they are less so at present. The Canterbury chapel Organ already cited (at *x*, ante), had both of its Man. to Ped. Couplers made with the Wedge and Sliding Sticker-Head. This Instrument also possessed two other Couplers—*Super Oct. to Great*, and *Pedal Pipes to Keys*—constructed in the same way. All these four Coupling-Actions were correctly designed, and worked quite satisfactorily.

aaa. As respects the *Adoption* of the Wedge, its abstract merits are of course involved in the question of the relative values of the Sliding and the Dropping methods of Coupler Contact: such appraisement must therefore be left to the *Department* COUPLING-ACTIONS,—with a third glance at *s*, next, and 90, *r* as a preparation therefor. A comparison between the *Block* and the *Cutting* varieties has already been made (at *y*, ante).

FITTING AND AFFIXURE OF KEY FRAMES.

b. First see that which is given under Head of POSIT,—at 92, *l* and on; and 93, *a* and on.

Having decided upon the actual placing of the Manual or Manuals turn to *Depart.* BUILDING-FRAME, where (at 43, *f*; and 44, *v*) a general indication of the best Treatments in Fitting will be found.

The Key-Frame of the Lowermost Manual will be fitted in its position by means of Wooden *Dowels*, and these will be preferably fixed into the proper parts of the *Building-Frame* or the *Key-Bench*, and *not* into the *Key-Cheeks*. When the Manual is fitted in *between* the Bui.-Frame *Middle-Rails* (see 43, *g*) there should be a Dowel projecting from the inner face of each such Rail; and the outer face of each Key-Cheek of such Manual must then receive a short horizontal Slot or Sinking, terminating at the extreme [tail] end of the Cheek, and corresponding with the Dowel. Two other Dowels will be fixed vertically in the Building-Frame or the Key-Bench; they will be set so as to be as near to Front-end of Manual as is practicable, and will enter the bottom edge of each Cheek of latter. A couple of *Screws* may be added, if desired.

The Key-Frame of the Second Manual will be fitted to the Lowest one *solely* by Four Dowels like the last, fixed, two in each Cheek, into the *upper* edges of the Lowest Key-Frame. The Third Manual, if present, will be fitted in the same way to the Second Manual: and if there be yet a Fourth Manual it will be so fitted to the Third.

Where the Vertical distance from the Keys of any Manual to those of one next to it is less than 3in. (see 92, *n* & on) it will usually be advisable to so cut away to a given point all the plain portion of the upper edge of the Cheeks of the Lower Manual as to leave the Finishes (see 86, *t*) of the latter standing *higher* than such edge. The Cheeks of the Higher Manual will thus have their bottom edges set at a *lower* level than the upper line of such Lower Finishes, and the front bottom corners of the Higher Key-Cheeks will lie just behind these Finishes.

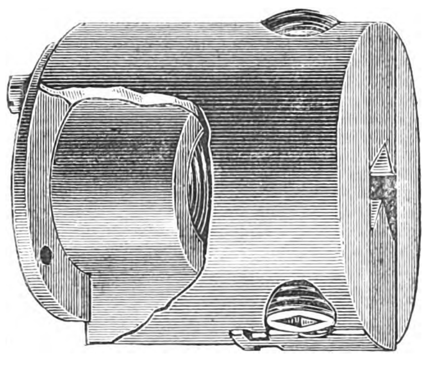
bb. An *Instance* of this last Treatment occurs in the Leominster Organ already mentioned, and sufficiently described at *x*, next.

(*To be continued.*)

IMPROVED DRILL-CHUCK.*

THE accompanying engraving represents an improved form of lathe chuck, made by Chas. H. Reid, Danbury, Conn. This chuck is very simple in the arrangement of its parts (which are few in number), and holds either flat or round drills, small material for turning, &c., as in making screws from long stock, or may be used for any of the purposes for which a small chuck is desirable; and especially where a strong grip is necessary. As will be seen, it consists essentially of a cast-iron body into which are fitted two steel jaws. One of these jaws has a V-shaped groove on its face, while the other is fashioned to a V-shaped projection corresponding with this groove. These are moved by the operation of a single screw turned by the means of a socket wrench. The angle of the groove in the jaw, as above referred to, is such that in combination with the different pitch of the ends of the screw which operate the two jaws, they are opened and closed at such respective velocities as to provide for any piece from the smallest to the largest which the chuck will take, being held exactly central.

Instead of threading the chuck to fit the lathe (as is commonly done) it is provided with a taper bush which is accurately fitted into a corresponding recess in the back of the chuck, this bush being threaded to the lathe spindle. It will be observed that this bush projects into the body of the chuck by which a long bearing surface is provided for keeping the two true, the one with the other; but what is of more importance still, by this means the overhang of the chuck beyond the end of the lathe spindle is not increased. An important object gained by the use of this bush is the practicability of using one chuck on several lathes in which the spindle screws are of different diameters or pitch; all that is necessary being to shift the bushes, of which as many as required may be provided at a trifling expense. In this way, if advisable, one chuck may be used on a half dozen different lathes, drill presses, &c. The jaws are made deep to provide a long clamping surface, and are arranged with a view to hold equally well the entire length of this surface.



ELECTRIC RAILWAYS.

A LECTURE on the utilisation of electricity for working railways was recently delivered before the Birmingham and Midland Institute, by Prof. Ayrton, F.R.S., who, in conjunction with Prof. Perry, has been making a special study of the subject. Engineers, said Prof. Ayrton, had been turning their attention to the consideration whether electricity might not supplant steam or compressed air for trains and for tramcars. The question was mainly one of expense, and what they had to consider was whether electric transmission of power would lead to greater economy than was possible to be obtained with an ordinary locomotive. The weight of a railway carriage filled with people was about seven tons, while the weight of a locomotive engine varied from twenty to sixty tons. Therefore the average weight of every engine might be taken as being equal to six carriages full of people. Ten carriages usually formed a train; therefore, the presence of the locomotive necessitated the expenditure of at least fifty per cent. more power than would be necessary merely to pull the train along. A still more serious objection to the use of the locomotive was that every bridge must be made many times stronger than would be necessary to carry railway carriages; and the repairs were many times as expensive. Compressed air had enabled the railway companies very successfully to apply brake-power to every wheel of a train; but it was to electricity that they must look to drive the train, by power applied to every pair of wheels. The electrical energy, however, must be produced either from the burning of coal, from the energy of the mountain stream, the forced stored up in chemicals, or the energy of the wind. At the present time it was the first of these—namely, the potential energy of coal, which was applied to railway propulsion; and it was that form which would still be employed even when they had electric railways, as it was found that the driving of a dynamo-electric machine by a stationary steam-engine would produce electricity more economically than it could be produced by the burning of zinc in a galvanic battery. By means of a small gas-engine, driving a Gramme machine, the lecturer showed how power was produced, which could be transmitted by wires, and made to work a lathe, a drill, or other apparatus at a distant point, and he explained that this method of producing electricity was the more economical by the fact that a pound of zinc only contained about one-seventh of the energy contained in a pound of coal, while the former was about twenty-five times as expensive. In employing electricity to drive a drill, flexible wires could be used to convey the current; but to drive a carriage along a railway, the simplest plan was to use the rails as the two wires, the one rail acting as the going wire, and the other as the returning wire—the electricity being taken into the electro-motor by the wheels on one side and sent back by the wheels on the other. The rails, however, must be insulated from one another, or the electricity would pass from the one to the other instead of going through the motor. It had been found hitherto impossible to insulate a long line of rails sufficiently to prevent excessive waste from leakage, and his colleague, Professor Perry, and himself had spent considerable time in devising methods to overcome this difficulty without adopting the method, which, however, had been successfully used for tramway purposes, or taking a supply of electricity with the conveyance by means of a Faure's accumulator. Instead of supplying electricity to a very long and badly-insulated rail, their plan was to place by the side of the line a well-insulated cable, by means of which the electricity was supplied to a comparatively small section of the railway over which the train was at the time running. As the train left one section and passed on to the next, a brush attached to it came in contact with a mechanical contrivance which transferred the electric current to the next section, and so on throughout the number of sections of which the line might be composed. Dr. Siemens had shown practically that an electric railway would answer over short distances, and the lecturer submitted that by making up the line of short lengths, each of which was automatically rendered electrical in its turn, the difficulty arising from leakage over an extended line was overcome. He showed the working of the system by means of a model circular railway about 10ft. in diameter, divided into four sections; and he pointed out that its arrangement afforded means by which an apparatus in a signal-box would show over what section a train was moving. Means could also be provided by which a train upon one section would effectually block the section behind it, so as to prevent all risk of collision by a following train.

WHALES.

ON the 3rd of November, 1827, an enormous whale was observed floating on the surface between Belgium and England. It was captured and brought to shore near Ostend, where it awakened lively interest. The skeleton of this animal—which was 85ft. long—was mounted and exhibited in many of the capitals of Europe, London included. It was afterwards taken to the United States, and European *savants* appear to have lost sight of it. Some ten years ago, however, the fact transpired that this once famous whale had turned up at in Kazan in Russia, was there bought by some magnate, and presented to the Imperial Academy of Sciences of St. Petersburg. It is now lodged in a corner of the Zoological Gardens in that metropolis, under a shed which affords but scanty protection from the elements. The ground is littered with bones that have fallen from it, and can be taken away by any who may desire some souvenir of their visit.

Such is the account of M. Van Beneden, the well-known Belgian naturalist, who has made the history of this whale, and the observations to which it gave occasion, the basis of an interesting lecture on the progress of cetology, lately delivered at a public séance of the Belgian Academy. We propose to give here an account of what he states regarding the zoological position of this animal.

The Ostend whale is a Balænoptera, this being the genus which comprises the so-called Rorquals or Piked whales. Here let it be said that the Family of Balænidæ or Toothless whales, comprises the genera Balæna, to which the Greenland or "Right" whale belongs, Balænoptera, Megaptera (the hump-backed whales), and Physalus, the Finner whales proper. What, then, is the exact position of the animal in question?

In 1827, when it was captured, and later, when its skeleton was shown throughout Europe, the most eminent naturalists were unable to determine this point. While the whale was in Paris, Cuvier had a plaster cast taken of the cavity of the cranium, and this, recently found by Gervais, contains no indication on the subject. Cuvier supposed that there was one species proper to the Mediterranean, and the differences of size observed in skeletons from the North Sea, were to him the result of mere differences of age. He really had not sufficient data for a precise opinion.

Now that skeletons of most of these animals are known, it can be affirmed that there are four distinct species (of Balænoptera), quite different in size, character, and mode of life, and that these species are no less known to whalers than to naturalists.

The first is the small Balænoptera, skeletons of which are to be found in most of our museums. It is the Balænoptera rostrata of Fabricius. It does not exceed 30ft., and one could not confound it with any other animal. It has yellow fins, and the vertebræ do not exceed 48.

The second species is much more rare; only a few skeletons have been obtained, one of which is in Berlin, another in Brussels. It has the name of Balænoptera laticeps, or, better, Borealis (the name given by Lesson before Gray), attains 30ft. to 40ft., and has more than 48 vertebræ.

The third species is the most common: it is the Balænoptera musculus. This is the animal which Cuvier believed peculiar to the Mediterranean. It does, in fact, sometimes penetrate into this sea, and is the only species the ancients knew. It attains some 60ft., and its fins are always striated.

The Ostend skeleton belongs to the fourth species, which attains 80ft., and the fin of which, dark and shiny, cannot be mistaken for those of other species. It is generally known as the Balænoptera Sibbaldii; M. Van Beneden considers it should be called the Balænoptera d'Ostende (as the much earlier name). In Greenland it is called the Tunnolik, in Iceland the Steypieydre.

The skeleton of Ostend was long the only one of its species; but this is no longer the case. There are others in London, Hull, Edinburgh, Gottenborg, Stockholm, and a couple, male and female, will shortly be possessed by Paris, obtained by Professor Pouchet last year in the Varanger Fjord, at Vadsö, where they are fished during the summer months.

Considering the observations recorded of their passage in Baffin's Bay, in the waters of Iceland, and of the Loffoden Islands, and their periodical appearance in the North of Norway, it may be said that this species is an animal of the North Atlantic. As for the individuals that have been captured on the coasts of Belgium, England, Scotland, or Sweden, they are probably vagabonds, repudiated perhaps by their kind, or sick and wounded individuals that have left their usual haunts.

Are these animals, which live on the Greenland Coasts, and pass from Baffin's Bay to the entrance of the White Sea, confined to the Atlantic?

Captain Scammon, who may be called the Scoresby of the Pacific, has carefully studied the marine animals of that Ocean; he has occupied himself with Balænæ, Megapteræ, and Balanopteræ, and one cannot but be struck on comparing the species he describes with those known in the Atlantic. There is in the Pacific a small Balænoptera not attaining 30ft., and another which exceeds 80ft., and the special characters of the skeletons and the fins recall so completely two of our species that one cannot refuse to recognise affinity.

Between the large and the small, there is another of middle size, Balænoptera velifera, which also recalls our intermediate species. We cannot doubt that the large Balænoptera sulphurea or "sulphur bottom" of the Americans, corresponds to our Ostend animal, and the Balænoptera Davidsonii to our small Rostrata. The intermediate species Balænoptera velifera appears to be our Balænoptera musculus.

Prof. Turner relates that an experienced whaler had said to him when he was dissecting a large Balænoptera, that he had often seen this animal in the Northern Seas, and that it was called silver bottom on account of the silvery appearance of part of its body. The word "silver bottom" seems to have become in the sailor's mouth "sulphur bottom." This same opinion is, moreover, expressed by Prof. Cope, of Philadelphia. The sulphur bottom is the largest species (he says), and it is the same animal that haunts the North of the Pacific and the North of the Atlantic. It is found on the coasts of California from May to September.

If we consider that it is the same free whale that haunts both the Sea of Ochotsk, Baffin's Bay, and the waters of Spitzbergen, the same species of Megaptera, of Cachalot, of Meluga, of Grindewal, and many other Cetaceans, we need not be surprised to find also the same Balænoptera.

The same forms are reproduced in the waters of our Antipodes. The British Museum received not long ago, a skeleton from New Zealand, quite similar to our small Balænoptera, and by the side of these lives a species which attains 80ft., and whose fins, vertebræ, and ribs correspond, both in number and form, to those of our large species.

A like observation may be made with regard to the South Atlantic. A son of M. Van Beneden, in a recent visit to Brazil, found in the species called Balænoptera bonnaesis, all the distinctive features of our Rostrata.

The *exposé* given by M. Van Benedon, in this lecture, proves clearly that our knowledge of cetaceans has undergone large extension within the last fifty years, though from the nature of the case great difficulties are encountered. We conclude with an anecdote in the lecture, which illustrates this, and also the activity and energy of Holböll, a governor of Greenland, now dead. One day Eschricht wrote to him, asking for the brain of a whale, as this organ in cetaceans was not well known. The letter was hardly gone when Eschricht bethought himself: "My friend Holböll will think me crazed, to ask such a thing. Even if he were an anatomist, how would he take it?" And he regretted not being able to send another letter retracting the foolish request. (There was only one courier to Greenland, leaving in spring.) What was the astonishment of the Copenhagen Professor to receive, by return of the courier, a cask of spirits, in which he found a complete brain of a hump-backed whale of ordinary size, perfectly preserved in its bony case.

DOMESTIC ELECTRIC LIGHTING.

A LECTURE on electric incandescent lamps suitable for domestic lighting was delivered in the concert-room of the Crystal Palace last week by Professor Silvanus P. Thompson, of the University College, Bristol. So far back as 1841 the attempt had been made to construct little electric lamps by enclosing in glass bulbs thin wires of platinum or thin strips of carbon, which on the passage of an electric current grew white hot. This method of procuring light from electric currents was revived in 1878 by Mr. Edison, who at first attempted to construct platinum lamps, which, however, in spite of many ingenious contrivances to protect them from over-heating, could not be kept from fusing up. Eventually Edison settled upon a filament of carbon, but not before a similar suggestion had been made by Mr. Swan, of Newcastle. Edison prepared his filaments from bamboo fibre, Swan from cotton thread. In each case the carbonised fibre was fixed in a small pear-shaped globe, and exhausted as perfectly as possible of air by a mercurial air-pump. A filament of carbon thus treated became as elastic as steel. Similar lamps had been constructed by Lane-Fox and by Maxim, with slight differences of detail in the manufacture These little lamps gave a light of about equal brightness to one bright gas-jet. They were destined to work a revolution in domestic lighting, since, when supplied by currents from a central station, they would not only be cheaper than gas, but would be far more readily managed and kept in order. There was no unhealthy smoke or products of combustion produced, very little heat, no smell, and no risk of explosion. The incandescent lamps lent themselves with extraordinary facility to the purpose of decoration, and would doubtless rapidly become the fashionable mode of lighting. The experience of the Savoy Theatre showed that it was practicable to apply them to a large building. The public safety demanded that no time be lost in making electric lighting imperative in all public buildings. It ought also to be made compulsory to use electric lamps in coal mines. In a few days the experiment would be tried of lighting the Holborn-viaduct and surrounding houses by Edison's lamps from a central station. This would be but a small sample of the method in which domestic electric lighting could be carried out on a large scale. The lecturer predicted for this method of lighting results far more important and wide-reaching than those which any other kind of electric lighting could possibly attain.

ELEMENTARY LESSONS IN DRY PLATE PHOTOGRAPHY.—III.*

The Dark Room.

OUR young friends will understand that the plates which they are about to work with are of the most "exalted sensitiveness;" that is to say, a very small amount of light allowed to act on them will produce a change which may be made visible. We must explain, however, that it is only certain rays of light which have the power of making the change which we mention. All our readers who have a little knowledge of physical science, know that white light is in reality a combination of light of all the beautiful colours which we see in the rainbow, and that if we pass a ray of white light through a prism, it will be broken up into all these colours. The order of them is—violet, indigo, blue, green, yellow, orange, and red. Those at the beginning of the list are called rays of high refrangibility, those at the end, rays of low refrangibility. Now, it is a curious fact that the photographic change which is worked in a sensitive plate is worked entirely by the rays of high refrangibility, principally by the violet and the blue, which are said to be "actinic"; whilst the red, which is said to be "non-actinic," has no effect at all. Were it not for this peculiar fact, photography would be almost impossible, because we could find no light in which we could manipulate our plates without their being affected and consequently destroyed. As it is, however, we only require to secure some place illuminated by those rays which do not have any photographic action, and we can work quite freely. In other words, we want a room lighted with only red light in which to work. Photographers give such an apartment the name of "dark-room," although the term is a misnomer.

---

* Condensed from the *Photographic News.*

In the dark-room, then, we propose to give what hints we consider necessary for the beginner. Any room or closet from which all the outer rays of light can be shut off may be converted into a dark-room in which plates may be changed and developed. If a room having a sink and water tap—say the pantry—can be "annexed," the trouble will be greatly reduced; but it is quite possibly to make shift with a pail for a sink, and a water jug instead of the tap. We have said that it is necessary to shut out entirely all outer light. This pre-supposes the use of artificial light for illuminating the apartment with the necessary red or non-actinic light. We consider that until such time as the student sees his way to fitting up a permanent dark-room, he will find it best to work with artificial light. There are lamps constructed especially for the purpose of giving "safe" light sold by all dealers in photographic apparatus. These use either gas, oil, or candles, and all consist of an arrangement whereby the air necessary to support combustion is introduced by passages which will not allow white light to find its way out, the colour of the light being modified by funnels of ruby glass, or shades ruby paper or cloth. The gas and oil-lamps are much to be referred to the candle arrangements, as with the former it is possible to raise or lower the light at will.

All, then, that the photographer has to do, is to find some small room or closet, which he can make quite dark, in which he can have a plain deal table to work upon, and to purchase a "dark-room lamp" from a photographic apparatus dealer. Our description of dark rooms would not, however, be complete, unless we say something about the fitting up of a permanent photographic room in which all the operations, including the manufacture of the plates, may be conducted.

A window is needed whereby the necessary light is introduced. It should be about two feet long, by one foot six inches high, and should be glazed with one thickness of ruby, and one thickness of orange glass. On the inside there should be a blind of red Turkey cloth, which can be raised and lowered at will. This is to reduced the amount of light when the sun shines direct on the window, or when the process of plate manufacture goes on. A sink made of glazed stoneware should have the top edge about two feet six inches, or two feet eight inches along the floor. The operating table should be covered with sheet lead, with a very narrow and low ridge round all the sides except that next to the sink, it should have a very slight incline in that direction, and should have the sheet lead "dressed" over the edge of the sink, so that all spillings may find their way into it. There should be a narrow shelf about four inches above the level of the table and sink, and extending along the whole length of both of them. On it is placed the lamp when artificial light is used, as when working at night, and the bottles of solutions actually used for development. The lower edge of the window should be an inch or two above this shelf. There should be a shelf about six inches below the operating table, on which the flat developing dishes may be kept. There should also be a table on which the levelling slab may be placed when the manufacture of plates is commenced. Above it—or, in fact, along all available space of the walls—shelves may be fixed for carrying bottles, &c.

A space is reserved for the drying cupboard, used in manufacturing plates. Above it, and with its lowest edge about three feet higher than the floor, should be fixed an ordinary cupboard, with a door closing light-tight. In this may be placed plates or anything sensitive to light, which would be destroyed if left about, for it must be understood that even light of the deepest ruby red will in time act upon a sensitive plate.

Double doors, whereby the photographer may go out or in without letting any light enter, are advisable.

Provision must be made for ventilating the room without letting in light. There should be at least one common gas jet for lighting up the room when no sensitive plates are about, so that solutions, &c., may be mixed with comfort, and there should be provision made for attaching several rubber tubes with the gas pipes for connecting with Bunsen burners, &c.

NOTE ON THE PHOTOGRAPHIC SPECTRUM OF THE GREAT NEBULA IN ORION.*

By William Huggins, D.C.L., LL.D., F.R.S.

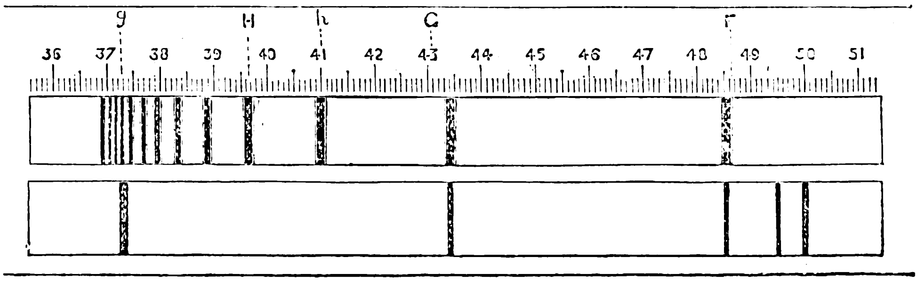
Last evening (March 7) I succeeded in obtaining a photograph of the spectrum of the great nebula in Orion, extending from a little below F to beyond M in the ultra-violet.

The same spectroscope and special arrangements, attached to the 18in. Cassegrain telescope with metallic speculum belonging to the Royal Society, were employed which have been described in my paper on "The Photographic Spectra of Stars" (*Phil. Trans.* 1880). The exposure was limited by the coming up of clouds to forty-five minutes. The opening of the slit was made wider than during my work on the stars. The photographic plate shows a spectrum of bright lines, and also a narrower continuous spectrum which I think must be due to stellar light. The bright stars forming the trapezium in the "fish's mouth" of the nebula were kept close to the side of the slit, so that the light from the adjacent brightest part of the nebula might enter the slit.

Outside this stronger continuous spectrum I suspect an exceedingly faint trace of a continuous spectrum. In the diagram which accompanies this paper the spectrum of bright lines only is shown, which is certainly due to the light of the nebula. In my papers on the visible spectrum of the nebula in Orion, and other nebulæ (*Phil. Trans.* 1864, and 1868), I found four bright lines. The brightest line, wave-length 5,005, is coincident with the less refrangible component of the double line which is strongest in the spectrum of nitrogen. The second line has a wave-length of 4,957 on Ångström's scale. The other two lines are coincident with two lines of hydrogen, $H\beta$ or F, and $H\gamma$ near G.

In the photograph these lines which had been observed in the visible spectrum are faint, but can be satisfactorily recognised and measured. In addition to these known lines the photograph shows a relatively strong line in the ultra-violet, which has a wave-length 3,730 or nearly so. The wide slit does not permit of quite the same accuracy of determination of position as was possible in the case of the spectra of stars. For the same reason I cannot be certain whether this new line is really single, or is double or multiple.

This line appears to correspond to ζ of the typical spectrum of white stars. In these stars this line is less strong than the hydrogen line near G; but in the nebula it is much more intense than $H\gamma$. In the nebula the hydrogen lines F and $H\gamma$ are thin and defined, while in the white stars they are broad and winged at the edges. The typical spectrum has been added, for the sake of comparison, to the diagram.



I cannot say positively that the lines of hydrogen between $H\gamma$ and the line at 3,730 are absent. If they exist in the spectrum of the nebula, they must be relatively very feeble. I suspect, indeed, some very faint lines at this part of the spectrum, and possibly beyond λ 3,730, but I am not certain of their presence. I hope by longer exposures and with more sensitive plates, to obtain information on this and other points. It is, perhaps, not too much to hope that the further knowledge of the spectrum of the nebulæ afforded us by photography, may lead by the help of terrestrial experiments to more definite information as to the state of things existing in those bodies.

P.S.—In the woodcut the new line is made broader to indicate its great relative intensity, and not to show its exact breadth.

EXPANSION OF WATER THROUGH ABSORPTION OF GASES.

Past researches on the absorption of gases by liquids have been limited mainly to determining the coefficients of absorption, that is, to ascertaining the quantities of the gases that are absorbed under special conditions. The changes of volume and density due to absorption have been but little investigated, and such investigation, when it has occurred, has been confined to a few gases that are strongly absorbed. The expansion of liquids in consequence of weak absorption has recently been made a subject of inquiry by Herr Knut Angström, who has a paper on the general subject in the February number of the *Annalen der Physik*. This includes the description of the somewhat simple apparatus he used, and the results furnished in absorption of various gases by water.

With regard to the method of exact determination of the volume-change in weak absorption, it was seen to be desirable, that each determination of volume should be made at constant temperature, that the gases used for absorption should be introducible without the liquid being exposed to evaporation, and that the absorbed quantity of gas should be capable of ascertainment with accuracy. These conditions were fulfilled in a somewhat modified dilatometer, for particulars of which, and its mode of use, we must refer to the original. The gases employed were atmospheric air, nitrogen, carbonic oxide, oxygen, hydrogen, and carbonic acid.

The results of experiment, collected in a table, prove that the increase of volume of water is proportional to the quantity of gas absorbed: a law previously arrived at by Messrs. Mackenzie and Nichols, also by Nichols and Wheeler, for carbonic acid and ammonia. It may therefore be concluded (the author says) to have general validity, at least within the limits of accuracy of the investigation.

Calling the increase of volume of the liquid through absorption of unit volume of gas δ, and the coefficients of absorption β, Herr Angström's experiments with distilled water yield the following values:—

Gas.	δ	β
Nitrogen	0·00145	0·0203
Atmospheric Air..	0·00140	0·0247
Carbonic Oxide ..	0·00127	0·0329
Oxygen..........	0·00119	0·0193
Hydrogen........	0·00106	0·0411
Carbonic Acid....	0·00125	1·7967

It would, perhaps, be premature, Herr Angström remarks, to draw from the values arrived at any conclusions as to the nature of absorption. One fact, however, may here be specially noted—viz., the small difference of the values of the expansion for gases which have otherwise very different physical and chemical properties. This is, doubtless, because we have not here to do with a chemical phenomenon, and that the molecules of the gases in absorption enter the liquid in a free state.

A calculation of the co-efficients of expansion, through absorption, for some easily condensable gases from older and less exact determinations, gave for muriatic-acid gas, δ = 0·00097; for ammonia, = 0·00077; and for sulphurous acid, = 0·00091. These values are pretty near those found above, so that a qualitative distinction between the absorption of easily-condensable gases and permanent gases does not seem to be warranted. This is still more clear on comparison of nitrogen, hydrogen, and carbonic acid; the first two are, at 0° C., and the pressure required to compress them to a volume corresponding to the volume-increase of the liquid in absorption, still permanent, while the last has passed into liquid condition. Yet the coefficient of expansion through absorption for the last gas lies between those for the first two. "For the rest," says Herr Angström, "the gas, in absorption, loses the properties belonging to it as a gas, especially the great mobility of the molecules, since this is opposed by that of the molecules of liquid."

Finally, Herr Angström compared the coefficients of expansion through absorption with the compressibility of the gases, and found that the series is the same for both properties.

LECTURE EXPERIMENTS.

An experiment for exhibiting the change in weight that attends oxidation or reduction, without the aid of a chemical balance, is given by Max Rosenfeld. A modified form of hydrometer takes the place of a balance. The ordinary saccharometer has attached to its upper end, by means of sealing-wax, a piece of strong wire, about 4in. long, and to the other end of the wire is fastened a glass cup, made by cutting the end off a test-tube. On the cup is placed a piece of platinum foil to hold the substance to be burned or reduced. The instrument is so adjusted that a weight of 0·8 to 1 gram on the foil will cause it to sink until the wire is a little way under water. It now resembles a Nicholson's hydrometer, and is very sensitive. To perform an experiment in oxidation, enough finely-divided iron is put on the foil to cause it to sink until the end of the wire is in the water. The foil, with its load, is carefully removed, and held over a flame until the iron is converted into oxide. When cold it is replaced on the glass cup, and causes the instrument to sink until the cup almost touches the water. To show the loss of weight by reduction, the foil is loaded with copper oxide until the cup nearly touches the water. After it is reduced to metal, of course, the apparatus sinks to a much less depth. A cylinder made of copper oxide and gum water, and well dried, can be used to show both oxidation and reduction.

---

* A paper read before the Royal Society

Brössler, of Vienna, has recently described several methods of making phosphoretted hydrogen for lecture experiments. He places some granulated zinc in a glass dish, and adds dilute sulphuric acid until bubbles of hydrogen gas are given off regularly, but not too rapidly. He then throws in a few pieces of ordinary phosphorus. In a short time the bubbles of gas begin to ignite at the surface of the liquid with a slight explosion. To hasten the operation, the dish and its contents may be warmed to 112° Fahr. on a sand-bath, or the necessary heat can be generated by putting the zinc in cold water, and pouring concentrated sulphuric acid upon it. If a solution of caustic potash and granulated zinc is heated to 140° Fahr., and a few pieces of phosphorus thrown into it, bubbles of the spontaneously inflammable gas will also be given off. The hydrogen generated by the action of concentrated hydrochloric acid upon zinc is not adapted to the generation of this inflammable gas, but the addition of a few drops of concentrated nitric acid produces the desired effect.

USEFUL AND SCIENTIFIC NOTES.

Prof. Boyd Dawkins on the Ancient World.—Last Monday Prof. Boyd Dawkins gave the fifth of a course of lectures on "The Ancient World at the Time of the Appearance of Man," at the Owens College. He said that it might be gathered from the association of living with extinct mammals that man made his appearance in India at the same hour, so to speak, of the geological clock as he appeared in Europe. The present order of things in India was shadowed forth at that time by the presence of the living species of mammalia. Europe, in the pleistocene age, was connected with Asia, so that animals at that time could freely wander from one to the other. The musk sheep, for example, had been traced from the Pyrenees right through Siberia by the remains which lay buried in the frozen morasses, and the mammoth of pleistocene Europe was found perfectly preserved in the frozen mud of the Siberian rivers. Indeed, almost the whole pleistocene mammalia, with the exception of the African species, were to be found also in Siberia, either living or frozen. Nor was their range bounded by Behring's Straits. The musk sheep, horse, bison, elk, reindeer, and the mammoth had been discovered in the frozen mud forming the cliff in Eschscholtz Bay, and had been traced over a large portion of North America. It was, therefore, evident that then Asia and America were united more closely than they are now, and the direction of their continuity was shown by the small depth of sea in Behring's Straits—some thirty fathoms. An elevation to that extent would unite the two continents together and form an isthmus. This group of animals was found as far to the south as the State of Kentucky, and there they were associated with gigantic extinct sloths and armadilloes, which belonged to the South American mammalia of the pleistocene age. Indeed, in North America, as in Europe, northern and southern animals were found mingled together, and there were three climatal zones implied by their distribution.

Ink for Rubber Stamps.—The following is said to be a good ink for use with rubber stamps. Aniline violet 90 grains, boiling rainwater 1oz., to which is added a little glycerine, and a small quantity of treacle. The quantities of the last two ingredients will vary with the season, but half a teaspoonful will be ample for the quantities of violet and water specified.

When an alloy of lead, tin, or other metal with sodium, is made in a melting-pot, great care must be used in subsequently freeing that melting-pot of all trace of sodium before using it for melting tin in it with a view to tinning copper or bronze articles; otherwise these articles, when placed in the melted tin, will be rapidly eaten away. This has been recently accidentally proved; but it might have been expected from known facts concerning sodium alloys as very long since pointed out by Mallet, who showed, among other things, that if a strip of iron be coated with sodium amalgam, and dipped into a pot of, say, molten tin, the iron will disappear faster than it can be put to the bottom of the pot.

SCIENTIFIC NEWS.

The following grants to learned Societies, &c., for the purposes of scientific investigation, appear in the estimates for the financial year:—The Meteorological Council, £15,300, which includes £800 for the gratis supply of forecasts to newspapers; the Royal Society, £4,000; the Royal Geographical Society £500, apart from the special grant for the Leigh-Smith relief; the Royal Society of Edinburgh, £300; the Royal Academy of Music, £500; the Irish Academy of Music, £300. The reports of the *Challenger* expedition will cost about £4,100 during the year, and the amount required for the expeditions in connection with the transit of Venus is nearly £15,000.

The death is announced of Herr J. J. Sievers, the astronomer, in his 78th year.

Differences of opinion appear to prevail as to the economy of the electric light; for while "professors" assert that it is cheaper, and prove their statements on paper, we find that it is being given up in places where it has been tried, notably at the Victoria Railway Station, Manchester. Last week, at the Society of Arts, Mr. Wigham read a paper on "Gas for Lighthouses," in which he had no difficulty in showing that gas was superior to oil, but also helped to prove that it was better, all things considered, than the electric light. Prof. Tyndall was in the chair, and had not a word to say for the electric light; but referring to Galley Head light, which is fitted up with Mr. Wigham's improved gas-burning arrangement, he said there could not be two opinions that the light was the finest of its kind in the world. The objections to the electric lights are that they are obscured by fogs and mists, and give false ideas of distance to the mariner. Steamships are, however, being fitted with electric lamps, and the "new" light is to be tried in the Law Courts.

An experimental train has been fitted up by the Eastern Railway of France with electric communication throughout, with brakes worked by electricity, and with electric lamps. The experiments with arc head-lights for engines are stated to be unsuccessful, the majority of drivers complaining that they cannot see so well on account of the dazzling effect.

Colonel Webber's paper "On Telephonic Communication," which was announced for the 22nd inst. at the Society of Arts, has been postponed until after Easter.

F. W. Webb, J. Reddrop, and M. H. Foye, of Crewe, have patented improvements on Lake's patent of 1879—Ancelin's acetate of soda warmer for railway carriages. The object of their patent is to insure the solidification in a crystalline form of the acetate of soda when allowed to cool after having been liquefied by heat.

Schmoele and Mols, of Antwerp, have patented a means of automatically playing musical instruments by pneumatic and electro-magnetic appliances. The pneumatic arrangements are for sounding reeds, and a sheet of card, perforated according to the tune, makes and breaks electric contact as it travels.

At the meeting of the Scottish Society of Arts last week, Mr. Lang read the report of a committee on Mr. Frazer's paper "On the Graduation of Thermometers." Mr. Frazer contends that thermometers graduated on the same scale for all parts of the instrument do not give correct indications of low temperatures, especially those below zero. We thought that fact was well known. At a meeting of the Engineering Section, Dr. Ferguson gave a lecture on dynamo-electric machines. After illustrating the conversion of mechanical energy into electricity, the lecturer proceeded to explain the distinction between magneto-electric and dynamo-electric machines, showing that the latter, in which the magnet was itself produced by an electric current, were capable of yielding, horse-power for horse-power, the better results of the two. The principle of the electric machine was stated to be magnetisation and demagnetisation. A detailed explanation was given of the respective modes of working of the Gramme, the Siemens, and the Brush dynamo machines; the lecturer concluding with the remark that the mode of testing their respective merits by candles per horse-power was rather unsatisfactory, from the circumstance that the number of candles set down for a given lamp might vary according to the position from which its light was gauged.

At a meeting of the Liverpool Science Students' Association last Saturday, Mr. Norman Tate, the president, suggested a subject for examination by the botanical section—the causes that lead to non-development of fruit in shrubs and trees near towns, notwithstanding profusion of bloom. An instance was given in the hazel, on the pistils of which one observer had found so much soot as to absolutely prevent pollenisation. A paper was read by Mr. C. E. Miles, on "Precious Gems," and Mr. J. Edwards described the process of diamond-cutting as carried on at Amsterdam.

The Eames locomotive was tried last week on the Lancashire and Yorkshire Railway, having been altered to suit the conditions required in passing another train. The firebox is 7ft. wide and 8ft. long; the tender carries 4,000 gallons of water, and 10 tons of coal. The engine has the cowcatcher, bell, and lamp, which are conspicuous appendages of the American type. We understand that it has been introduced to show the capabilities of the Eames vacuum brake, and also to prove that it can run without stopping for a longer distance than any English locomotive. Not much difficulty is experienced in replenishing the tender-tanks without stopping on the North-Western line, and possibly an arrangement could be devised for picking up bags of coal if it were necessary.

The Society of Arts Bill for the Amendment of the Patent Law has been brought in by Sir John Lubbock, Mr. W. H. Smith, and Mr. J. C. Lawrence, Q C. The second reading of the Bill is set down for Wednesday, April 5.

It having been stated that Mr. C. L. Wragge was about to resume his observations on Ben Nevis, that gentleman has written to say that they will probably be continued during the summer, but no definite arrangements have yet been made.

A new pump for gas-compression, which appears likely to be serviceable in the laboratory and in industrial operations, has been described to the French Academy by M. Cailletet. A distinguishing feature is the use of a mercury column above a plunger-piston, the two working up and down in a vertical cylinder. The gas to be compressed enters by a lateral tube, in which is a stopcock worked by cams. At each revolution of the flywheel about 1 litre of gas is compressed; so that, with an hour's work, one may obtain 400 or 500 grammes, e.g., of liquid carbonic acid or protoxide of nitrogen. When the compressed gas acquires sufficient tension, it raises an ebonite valve at the top of a narrow passage, and passes through a tube to the receiver, which is formed of metallic tubes arranged in bundles, and communicating with each other. In these, gas compressed to several hundred atmospheres may be kept safely. Glycerine or vaseline is used to lubricate the working parts of the pump. The apparatus requires but a small motor force; there is no admixture of air, and heating is avoided, as the heat liberated in compression is spread, by movement of the mercury, through the mass of the cylinder, which cools quickly, without a circulating current of cold water being required.

A central laboratory of electricity is to be instituted in Paris, under the supreme direction of the Ministry of Posts and Telegraphs. The sum of 325,000 francs from the profits of the recent Exposition will be devoted to its organisation and maintenance.

The objectionable dark coating which most bronze statues soon acquire, with the look of cast-iron, does not consist (according to Herr Brühl) of sulphuret of copper, as commonly supposed; but of a mixture of coal-dust, sand, &c., with oxides of the bronze-metals. It is not removable, either mechanically, or by treatment with dilute sulphuric acid; but, on the other hand, it may be very quickly and completely washed off by means of a concentrated solution of carbonate of ammonia, applied with brushes. Thereupon a layer of patina is formed, which guards the statue against fresh formation of the dark coat. The work should, of course, only be intrusted to skilled and intelligent men. Another method is to paint the statue, at intervals of a few weeks, repeatedly with a solution of 20 parts anhydrous vinegar in 100 parts bone oil. The acetate and oleate of copper salts thus produced, form first a thin green layer, which hinders the attachment of dirt and dust, and occasions further patina-formation.

Some interesting results concerning the penetrability of porous bodies by air have been recently obtained by Herr Christiani, using what he calls a *poroscope*, which consists of a brass cylinder, closed by two capsules, and having, at about the middle, an annular partition, in which cylinders of the bodies to be tried are inserted air-tight. The first substance he used was red beech-wood, and with this the motion of one capsule induced a corresponding motion of the other. A building-stone of the densest kind (clinker) behaved similarly, only a difference of phase was noticed in the motions. Old, dry oak, ivory, cork, and (what is specially noteworthy) a disc of a new earthenware cylinder of a galvanic element, proved quite impermeable by atmospheric air. In a later series of experiments, different kinds of wood were compared in the fresh and in the old dry state. Fresh oakwood was here found permeable; and this is botanically instructive, because moistening the end-surface of a permeable boxwood cylinder rendered it impermeable. Herr Christiani has devised another apparatus for measurement of the phenomena, consisting of two mercury manometers, communicating by means of caoutchouc tubes through the poroscope, and he will ere long publish observations made with this.

The well-known works of Krupp are now under contract with Brazil to supply 18 batteries, or 108 complete field-guns, within the present year. Roumania has lately ordered 100 of Krupp's guns, and Sweden and Norway 30. Since 1873 more than 10,000 guns have been sent out from these works.

The telephone-cells or chambers in the Berlin Exchange have double walls, with ashes, clay, or sawdust in the interval. Under the wall-papers is cotton-covered felt stretched on a framework, beyond which is a lining of thin pasteboard. This is quite successful, and the cells are much frequented. There are at present in Berlin two public telephone-rooms, and in Hamburg one, into which a person may go and, on payment of about 5d., converse with any one who is in the telephone system of the city.

An instructive series of experiments on the Faure secondary battery has been described to the French Academy by M. Allard and four other physicists. Thirty-five elements (new model) were employed, a Siemens machine was used in charging, and the discharge was through a series of Maxim incandescent lamps. It appears that a work of 6,382,100 kilogrammetres was stored in the battery (being 66 per cent. of the work expended). Of this 60 per cent. was recovered during discharge. Thus, the use of the accumulator involved a loss of 40 per cent. of the electric work disposable without it. It is pointed out that there are many cases in which this loss would be fully counterbalanced by the advantage of having at hand, and quite at disposal, an abundant source of electricity.

The general proportion of carbonic acid in the air has now been sufficiently determined (in M. Dumas' opinion), by M. Reiset's experiments, as about 3 volumes in 10,000. M. Dumas suggests the importance of now studying the variations to which it is subject through great movements of the atmosphere; and for this purpose the approaching transit of Venus expeditions, to various portions of the globe far apart, afford a valuable opportunity.

It has been lately observed by Prof. Detmer, that various substances do not act in the same way on living plant cells and on ferments. Thus, while (not too) dilute common salt solutions and oil of cumin are very poisonous to plant cells, they do not arrest the action of diastase on starch. This is adverse to the view that life is to be conceived as a kind of ferment action.

The subject of injury to health from tinned meat has been engaging some attention in France. A Nantes chemist, M. Bobierre, found that in many cases the soldering, hastily done, had been such as to bring a considerable surface of the solder (containing sometimes as much as 45 per cent. of lead) in contact with the meat. M. Bobierre calls attention to the inequality of legislation with regard to these imported meats, and the national products of like nature, the latter being now under strict regulations as to the mode of soldering (which were issued in August last after revelations by MM. Schutzenberger and Boutmy). A rapid and sure means of detecting impurity in the tins employed in tinning having become a desideratum, such a means has been lately submitted to the French Society for Encouragement of National Industry, by M. Maistrasse. It is based on the different aspects presented by the *moires* (or wavy combinations) obtained with alloys containing a greater or less quantity of tin, when the metallic surface is washed with pure hydrochloric acid mixed with a little nitric acid. By patient and methodical researches, M. Maistrasse has succeeded in forming a series of *moire* types, tin and lead, in which the proportion of lead increases from 1 to 30 per cent.; the difference, in this respect, between pure tin and an alloy begins to be very sensible whenever the amount of lead exceeds 5 per cent.

At the Paris Exhibition, an instrument which excited much curiosity was the *fan-fare* of M. Aden, a trumpet-arrangement which amplified to the strength of a hunting-horn airs sung lightly into the transmitter of a singing condenser. The mechanism by which this was accomplished is now made known in *La Lumière Electrique*. It consists of a horseshoe magnet, having at its polar extremities two flat bars of soft iron turned towards each other (so as nearly to meet), with flattened coils not reaching the extremities. In front of these ends is a small, very light armature, supported on a small wooden knob, which is attached to a very thin slice of pine, which forms the vibrating diaphragm. It is in front of this diaphragm that the resonance-case is placed, into which the trumpet is inserted. The distance of the small armature from the magnetic poles is so regulated that at the moment of action of the current a shock occurs, and the repetitions of these shocks gives the resultant notes. It has been attempted to apply the system to reproduction of speech, but the few words obtained were so indistinct that the idea was given up.

Prof. Tyndall on Light, Sound, and Heat.—On Thursday week Prof. Tyndall, D.C.L., LL.D., F.R.S., delivered before a crowded audience in the theatre of the Royal Institution, the first of a course of three popular lectures on "The Resemblances of Sound, Light, and Heat." He began by reminding those before him how science had been slowly built up from the beginning by the constant interaction of two factors—the phenomena of nature and the human mind. At first observation by means of the outward senses was deemed sufficient. But by degrees the root of things was asked for, and this could only be seen by the eye of the mind. He had to speak to them of wave motion, such as that of the ocean, on whose undulations every drop of rain exerted an influence. The formation of ripples on large or small bodies of water was illustrated and explained. From the discussion of the propagation of the waves in water the lecturer passed to speak of like movements in the atmosphere. In an illustrative experiment sound was passed along a series of balls, each hung on a metallic spring, to render visible what the Hon. Robert Boyle had called "the spring of the air." It was thought that the idea of the pulsations of sound had suggested to the Huygens the explanation of the phenomena of vision by his undulatory theory of light. Newton and he had wrestled like two giants on this question, our own great countryman insisting that light was produced by the impact of particles, while his antagonist thought it was caused by waves of luminous ether impinging on one another. The controversy was critically reviewed at some length, the chief experiments and illustrations being repeated with all the modern improvements. The laws of the reflection of sound and light alike were deduced logically from wave motion. A parallel explanation of the nature and laws of refraction, applicable severally to optical and acoustic science, was given, and reference was made to the merits of Snell, who developed the law of refraction before the days of Newton and Huygens, and of the Californian investigator, Leconte, Professor Barrett, and Lord Rayleigh. The lecturer concluded with the repetition, amid much applause, of the photographic illustrations of animal life in motion given recently at the Royal Academy by Mr. Muybridge, of San Francisco.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

ICI ON PARLE FRANCAIS—PRECESSION OF THE EQUINOX—GREGORIAN AND CASSEGRAINIAN TELESCOPES—COMITES TO ALDEBARAN—BARLOW LENS—FINDING THE—MOON'S POSITION—THE CALCULATION OF A SOLAR ECLIPSE—ARAGO'S "POPULAR ASTRONOMY."

[19826.]—The receipt of the first part of "L'Astronomie," by Camille Flammarion, certainly suggests the idea to me that among things which "they order better in France" is the production of Monthly Astronomical Reviews. Beautifully printed, with its 40 large octavo pages illustrated by nine wood engravings, this new magazine, which only costs a franc to subscribers, presents a remarkable contrast to its skimping little predecessors for which we are charged a shilling a number in England. Let us hope that their Editors will take a hint from M. Flammarion's example.

In reply to "Astrologos" (query 46299, p. 19), the vernal intersection of the Equator and Ecliptic, the "First Point of Aries," or ♈ of the Almanacs, quitted the extreme S.W. of the Constellation Aries about 259 B.C. It then crossed the little bit of Cetus, which runs in between Aries and Pisces at this point, and 104 B.C. entered the N.E. portion of Pisces, across which, as your correspondent knows, it continues to travel. By the year 2720, or thereabouts, the Vernal Equinox will be found in the confines of Aquarius.

"G. L. E." (query 46333, p. 20) will simply waste his time and money, should he attempt to construct either a Gregorian or Cassegrainian telescope with its mirror ground to *spherical* curves. Notably in the case of the Gregorian, it is essential that the large mirror should be a segment of a paraboloid, and the small one a segment of an ellipsoid of revolution, if aberration is to be destroyed. If we grind both these mirrors to spherical curves, not only will their aberrations unite, but that of the large mirror will be extremely intensified by the action of the smaller one. In the case of the Cassegrainian form, the small mirror should be of a convex hyperbolic form, instead of a concave elliptic one. In one sense, its convexity would be less likely to exaggerate the aberration of the large mirror (assuming this to be spherical) than would the concavity of its counterpart in the Gregorian form; in fact, it would have a tendency to correct it. Of course "G. L. E." knows that the Cassegrainian telescope inverts objects. The distortion in a Gregorian with spherical mirrors would be monstrously greater than that in a Newtonian of equivalent focal length.

I am afraid the "Zenas" (query 45836, Vol. XXXIV., p. 483), will begin to think that I have forgotten the promise I made in letter 19741 (p. 589 of the same volume) to look at his *comites* to Aldebaran. This, however, is not the case. I first tried what I could do with the ordinary position micrometer, but the illumination of the field rendered the Southern *comes* exceedingly difficult to see at all, and absolutely obliterated the one preceding Aldebaran. After this, the weather was very bad, and, moreover, moonlight intervened. We have, though, at last had two or three brilliant moonless nights, and I have availed myself of them to make the best estimate I could of the measures for which "Zenas" asked. His first *comes*, then, the one at an angle of about 185° with Aldebaran, is a 11—12th magnitude star, and is about 340″ from its primary. This is rather brighter than the well-known companion. Then the one at an angle ± 250° is a 12—13th magnitude, and is approximately 308″ from α Tauri. I trust by this time that "Zenas" has picked up the recognised *comes*. He will see it plainly enough if he will hide Aldebaran behind a bar for a few seconds: and, once caught, it will be visible enough even in the glare of the large star.

In answer to query 46371 (p. 43), the crown glass lens in the Barlow combination is the concave one, and is placed next to the object-glass, the convex flint lens being obviously next the eye-end of the telescope.

The arrangement of "W. L. O," as described in query 46389 (p. 43), seems quite sufficiently accurate for his purpose. It is not rigidly so; because, for example, the Moon would be vertically over the Eastern part of New Guinea when she was new on February 17, and not over its centre; but, as I have said, this appears near enough for obtaining a general notion of her position with reference to the Earth's surface at any given time. With regard to the beginning and end of a Solar Eclipse, my querist seems to be confusing two different things: the time occupied from its beginning to its end *on the Earth generally*, and those at any given station. If we suppose an observer to be situated at the centre of the Sun, the instant that the Moon's preceding limb touched that of the Earth would be that of the commencement of the Eclipse on the Earth generally: as that of the contact of her following limb with the opposite one of the earth, would mark its termination. On the other hand, at any particular place where the eclipse was total, its duration would amount roughly to the time occupied by the Moon in travelling over two of her own diameters in the sky + the apparent increase in longitude of the Sun during the interval. The greatest, and least, possible duration of an Eclipse varies, moreover, with the latitude. Now, supposing even that "W. L. O." gave the specific stations for which he wishes to know the greatest and least times a Solar Eclipse can take; to furnish a reply would involve an amount of most operose calculation which I have neither the time nor the inclination to face. So difficult is the computation of any given phase for a given place, that it can only be performed by successive approximations. I may add that, on the Equator, the longest possible duration of an Eclipse of the Sun from the instant of first to that of last contact is 4h. 29m. 44s. As for the lines on the map, perhaps I may just say this much: Supposing the observer to be on the Sun, then the line marked "Eclipse begins at Sunrise," passes through all those places where the Moon is entering on that terrestrial limb just being brought into view by the Earth's rotation. "Northern line of simple Contact" and "Southern line of simple Contact" are drawn at the extremities of a Lunar diameter. Every place on the Earth's surface situated between these lines must, ex necessitate, see more or less of the Sun's disc obscured. Those on the Northern line will see the Moon's Northern limb tangent to the Southern one of the Sun, and *vice versâ*. This may give your correspondent some notion of the principle on which the maps in the *Nautical Almanac* are drawn. For details I must refer him to Chauvenet's *Spherical and Practical Astronomy*, Vol. I., pp. 436 to 517.

I question exceedingly if the maps at the end of Smith and Grant's translation of Arago's "Popular Astronomy" (concerning which "S. M. B. G." puts, query 46401, p. 44) were ever intended to give anything more than a general idea of the face of the Heavens. Assuredly small differences of stellar magnitude are unnoticed in them. Bayer and Flamsteed are both quoted on two of the maps at the end of Vol. I. as authorities, as are Lacaille, Bode, and Piazzi. Probably Flamsteed's Atlas formed the basis of the maps, and the objects wanting in it were supplemented, with their magnitudes, from the catalogues of the observers named. Doubtless, though every star between, say, the second and third magnitudes, but nearer to the former, was called a second mag., while, perhaps, a very small 4th would figure as a 5th. In my copy of Arago, Castor and Pollux are not reversed, Castor being quite properly the Northern Star. Finally, there is no *Constellation* of "Duo Asini"; albeit these words are engraved in capital letters. They refer to γ and δ Cancri, which (according to Smyth) the Romans called Aselli, the Greeks ὄνοι, and the Arabians (following Ptolemy) Al-himâraïn—all signifying the same thing, the two asses. The origin of this term I have been unable to trace.

A Fellow of the Royal Astronomical Society.

COMPARISON OF STAR MAGNITUDES.

[19827.]—SOME little time ago I compared the magnitudes of every star in the "Bedford Catalogue" with those of Σ. in the *Mens. Micr.*, and I have thought that a brief collation of the results (which are in gratifying accordance with those given by Mr. Knott), might be of interest to some of the readers of the ENGLISH MECHANIC. I have restricted the comparisons to the objects measured with the Dorpat refractor in the *M.M.*, because the magnitudes in that work are far more carefully estimated by Σ. than those in the *Cat. Novus*, and I have omitted any reference to the *Pos. Med.* because of the difference in the size of the telescope employed; moreover, the mean epoch of the observations of the *M.M.* more clearly approximates to that of Smyth than either of the others. The following little table explains itself.

Sm.	Σ.	No. of comparisons.	Extremes.
9·5	8·78	18	ε Drac. 7·6; 67 P. x Leonis 9·7.
10	9·18	25	46 Herc., 59 Cygni 9·0; 20 Persei 10·0, α Aquilæ 10·2.
11	10·10	26	39 Erid. 80 H viii. Persei 9·2; α Androm. 11·2, 81 P. viii. Mon. 11·5.
12	10·17	17	136 P. xvi. Herc., 88 P. xvi. Oph. 9·0; β Delph. 11·0, α Tauri 11·2.
13	10·65	21	φ Virginis 9·7, 307 P. xix. Aquil. 10·0; 72 Virg. 11·5, η Serpent. 12·0.
14	10·36	(6)	84 Ceti 9·2; 54 Oph. 11·3.
15	11·15	(8)	ν Ceti 9·6; ξ Pegasi, 16 Lacertæ 12·0.
16	10·83	(3)	

Smyth's 10th mag. includes 4 stars rated 10½m. by him; his 11th two 11½ mags., his 12th one 12½m., and his 13th one 13½ mag. star. It is unadvisable to carry the comparison above Smyth's 9½ mag., because many of his 9 mag. stars are assumed from Piazzi. It does not seem to be generally known that where both components of a double star observed by Smyth are to be found in Piazzi, Sm. has usually assumed Piazzi's mass for *both* components, as in the case of γ Delphini, 38 P. II. Triang., 1 Camelop, &c.

The following comparison by O.Σ. of the magnitudes assigned by himself at Pulkowa with those of his father at Dorpat, may be of use:—

Σ.	O.Σ.	No. of Comparisons.
12·0	11·35	10
11·0	10·38	20
10 0	9·64	59
9·0	8·80	165
8·0	7·90	159

It will be remembered that the *min. vis.* in the Dorpat refractor was placed by Σ. at the 13th mag. of his scale in the *M. M.*, and at 12·4 in the *P. M.*, the smallest *measurable* object being called 12·0m. There is only one 13m. star, as far as I remember, in the whole of the *M. M.* O.Σ. has said of the magnitudes assigned by him to objects seen in the Pulkowa refractor, "I estimate a star to be of the 14th magnitude if it is more suspected than distinctly seen on a dark night." This would be about the fifteenth mag. in his father's scale extended, agreeing excellently with the theoretical value.

H. S.

COMETS AND METEORS.

[19828.]—IN the interesting lecture by Dr. Huggins, given in the "E. M.," it is stated, as the result of experiments with several meteorites, that their spectra were similar to that of comets apparently in all the cases tried, and this notwithstanding the disadvantage of examining the meteorites necessarily "after superficial ignition in passing through the air." I presume other lines could be made to appear which would differ probably in different meteorites, the cometic lines being preponderant. This being so, I do not quite comprehend the lecturer's objection to the suggestion of Professor Tait that the luminosity of the parts about the nucleus might be due to the mutual impact of the fragments,—namely, that the spectra would be more complicated, and not the same in each comet. Now, the cometic spectra are not all absolutely identical, though similar, and all we have to suppose is that in each comet, as in the meteorites experimented upon, there is some volatile mattor, very similar in all, whose lines are predominant.

As to the suggestion of Prof. Stokes, that in the vacuum of the planetary space the loss of heat by radiation would be very small, and that we should consequently have a high temperature, this, I think, extremely doubtful. Some comets manifest the characteristic tails at distances from the sun equal to that of the earth, and whatever be the nature of the vacuum or luminous fog which surrounds a comet, the moon must be practically surrounded by something similar in density. Now, at the lunar surface at all events, we see nothing analogous to the comet lines or electrical action sufficient to produce bright-banded spectrum, notwithstanding the circumstance that we are so many times nearer that body than we are to comets.

W. C. E.

TO ALFRED H. ALLEN—ANALYSIS OF REFINED COPPER — HARDNESS OF WATER — TANNIN — IMPURITIES IN ACIDS—BLEACHED BEESWAX—GLYCERIN—PRECIPITATING ALCOHOLIC SOLUTIONS—ANÆSTHETICS.

[19829.]—IN reply to query 46068, page 578 of last volume, addressed "To Alfred H. Allen," I fancy "Cupric" would find Volhard's method the best for estimating the actual amount of copper in the commercial metal. Some time since I obtained exceedingly accurate results by means of it, and it has the advantage of being unaffected in its indications by the presence of any metals except mercury and silver. It consists in adding sulphite of sodium to the slightly acidulated solution of the metal, warming, and then adding a moderate excess of a standard solution of ammonium sulphocyanide. The liquid is made up to a definite volume, passed through a dry filter, and an aliquot portion of it titrated with decinormal nitrate of silver, using a few drops of ferric sulphate as an indicator. As soon as the whole of the sulphocyanide is precipitated, the reddish tinge disappears, owing to the destruction of the ferric sulphocyanide. It is well to add the silver solution in slight excess, and then to titrate back with sulphocyanide. Of course the amount of copper is calculated from the amount of sulphocyanide which was removed from the solution in the form of CuCNS. Chlorides must be absent.

For the detection and estimation of sulphur in commercial copper I should recommend the querist to dissolve the metal in nitric acid, evaporate to a low bulk, dilute, filter, and precipitate the liquid with barium chloride. He must take care that the insoluble residue does not retain sulphate of lead. I don't know Hampe's method of determining suboxide—at least, I don't know it by that name.

"Dyer" (query 46109, page 579) will find full descriptions of the method of ascertaining the "Hardness of Water" in any book on Chemical Analysis—e.g., Frankland's "Water Analysis," Wanklyn's "Water Analysis," Sutton's "Volumetric Analysis," Thorpe's "Quantitive Analysis," &c.

Probably the querist ("Tannin," No. 46110, page 579) could prevent his gelatine solution from spoiling by adding to it a little salicylic acid. It would be worth trying at any rate.

In reply to "Impurities in Acids" (query 46199, page 624), "W. Duff, Analytical Chemist," gives some curious information. Has he *tried* whether he can get a "blue" ppt. by adding potassic ferrocyanide to a sample of oxalic acid? Fancy, too, adding ammonium oxalate to a solution of oxalic acid, in order to detect lime! Again, he distinguishes lime from alumina by adding ammonium carbonate. But perhaps the grossest error is the direction to test for sulphurous acid in hydrochloric acid by adding "a few drops of strong sulphuric acid," and noting if there is a smell of burning sulphur.

"Bleached Beeswax" (query 46291, page 627) is liable to a number of sophistications. The following is a simple and apparently a fairly good method of qualitatively examining suspected samples. Dissolve a portion of the wax in turpentine, when any mineral or starchy impurities will remain undissolved. Sulphur may be recognised by the smell of sulphur dioxide, produced by burning the wax previously made into a taper. Rosin gives wax a terebinthinate odour, and makes it adhere to the teeth if chewed. Paraffin makes the wax brittle. Lard is indicated by the fatty odour and feel of the sample. Other and more reliable methods will be found in "Commercial Organic Analysis," Vol. II.

"Inquisitive" (query 46298, p. 19), asks me to tell him the best method of recovering "glycerine" from soap lyes on a large scale, as its value has lately advanced so enormously that its extraction has become a desideratum. There are several patented methods of effecting this purpose. These the querist could not use without payment; secret processes I cannot describe; and "Inquisitive" will scarcely expect me to give him the benefit of any private ideas I may have on such a matter. However, the querist will find some information in a reply by Mr. F. Barker Cooke, on p. 40, and some more on p. 29. I see Mr. Cooke falls into the old error of supposing glycerine to be soluble in chloroform, whereas it is in reality wholly insoluble, and consequently his method of separating glycerine and sugar is absolutely unworkable. Palin appears to have been originally responsible for the statement as to the miscibility of glycerine with chloroform, and the persistency with which various authors have copied a statement which is improbable on the face of it, is a striking example of the recklessness of the bookmakers. Glycerine is often very impure. That intended for medicinal use should leave no sensible ash on ignition, should be neutral on reaction, and unaffected by strong sulphuric acid, nitrate of silver, sulphuretted hydrogen, oxalate of ammonium, or exposure to sunlight.

For "Precipitating Alcoholic Solutions" of resins (query 46416, page 44), a good plan is to add a few drops of a solution of alum or chloride of calcium, and then add a little phosphate of sodium. The flocculent precipitate entangles the finely-divided resinous particles, and filtration becomes easy. Whether this method would be applicable to the case of the querist depends on whether a salt of calcium or aluminium would be injurious to his solution. But it is not difficult to produce a flocculent precipitate of some sort without removing any of the active constituents of the liquid.

"Anæsthetics" (query 46391, page 44) vary much in their effects, according to their purity. The objectionable symptoms sometimes attending the inhalation of chloroform are most probably due to the presence of other bodies. Ethylidene, or ethydene dichloride, is prepared by the action of chlorine on ethyl chloride, or by distilling aldehyde with pentachloride of phosphorus. When pure it boils at 60° C., and has a density of 1·186 at 12° C.

Alfred H. Allen.

Sheffield, March 18.

ORNAMENTAL LATHE-THREADS.

[19830.]—We have to thank "Scorpio" for his valuable letter. Of course, all these data may be got by trigonometry; but the mathematical formulæ are not sufficient for practical readers. Should Mr. Holtzapffel not favour us by comcompleting his explanations, perhaps "Scorpio" will kindly work out the actual sizes of the screw-shafts at bottom of thread, and publish them in "E. M."

As thousands of the present ornamental lathes are in circulation, a complete summary of the data will be of practical value in the pages of the English Mechanic, so that its readers in any part of the world may be able to understand these "ornamental screw-threads." I propose, therefore, to collate our present fragmentary data in the form of a convenient table, and ask the Editor to favour us by publishing it. Meanwhile, I shall be grateful to anyone who will make accurate measurements from his own apparatus for the data which I have requested, and who will kindly forward them to me by a private note.

We want the sizes—outside the thread, and the screw-rates of all ornamental mandrel-noses; also the diameters of their lathe-bits. Sizes should be measured in thousandths of an inch; or a template of card, tin, or thin copper may be cut so as to slide accurately over the nose, outside the thread, which will give its diameter. Sealing-wax impressions of screw-threads will give their screw-rate accurately. Such measurements, templates or impressions, with descriptions of the apparatus from which they are taken, may be forwarded by post.

James Edmunds, M.D.

Grafton-street, Bond-street.

[19831.]—I quite agree with "Orderic Vital" in that Mr. Evans made a mistake in taking offence at Dr. Edmunds' letter. Dr. Edmunds goes at once to the root of a question which is of great importance to amateur turners, and he calls a spade a spade. He is quite right in saying that the present ornamental screws are "a barbarous survival of rule-of-thumb mechanics," and that amateur turners are "victimised" by unwittingly purchasing costly apparatus constructed with obsolete and incommensurable screw-threads. Charles Holtzapffel, a whole generation ago, said that these threads ought to be superseded by making all new screws to aliquot parts of the inch. As a client of Mr. Evans, I trust he will allow me to ask him whether these old screws should not now be superseded by aliquot threads? Is there any reason why Dr. Edmunds' suggestion to screw new 5in. mandrel-noses ten threads to the inch, and 6in. mandrel-noses nine to the inch, should not be adopted? Will Mr. Evans favour us with the sizes and threads of his present ornamental mandrels? Infinite simplicity, and comfort, and saving would accrue, by getting rid of mandrel-noses screwed 9·45 to the inch, and while some may look to Mr. Holtzapffel, others will look to Mr. Evans, for help in the matter. If a maker will go on repeating the undeveloped nomenclature, and reproducing the obsolete models of his grandfather, the end is clear—he will be superseded by newer men, who do not insist upon using up old patterns and selling off obsolete screw-tools, and who have the freshness and capacity to advance with the progress of science.

I note that Mr. Holtzapffel does not give us the remaining data for which Dr. Edmunds has asked, and which are necessary to enable us to understand these screw-tools. Probably, Dr. Edmunds does not yet realise the fact that these data are not given, simply because they do not exist. The size of the drills for boring out holes to be tapped for those screws are taken by "rule of thumb." The gauge-plates, as they are called, do not contain any second hole for sizing the drills or testing the screw shafts at bottom of thread, as all properly-arranged *systems of screws* do. The only way is to put the drill into the screw-hole, and see if it is about the size inside the thread. Of course, this leads to a rapid deterioration of the screw-holes, which ought to be preserved intact, in order to gauge the finished screws. I think we shall find that, after all Mr. Holtzapffel's professions of not making an enigma of anything, and of willingness to answer Dr. Edmunds's questions about these screw-tools, he is reluctant to make a clean breast of the facts, and that he still wishes to make a property of these screws. If he can do this, future generations of purchasers must still pay for sets of screw-tools, and for repairs which can be done nowhere but in his shop. But the progress of science cannot be stopped for any man's private profit, and amateurs will certainly look to other markets for their apparatus if these screws are still forced upon them. I trust that Dr. Edmunds will not leave this question where it is.

A Member of the Amateur Mechanical Society.

SCREW THREADS.

[19832.]—Referring to "Scorpio's" letter, No. 19819, it is all very well calculating the depth of a thread by some trigonometrical formula with a view to ascertaining the size of the hole that has to be tapped; but practically I can assure him that such a formula would be of little or no use in the shop. Individually, I may say that his notation as, *e.g.*, $\frac{1}{2}p : d =$ tan. $\theta / 2$ is as incomprehensible to me as a poem by Longfellow or anybody else would be if I read it.

The difference in diameter between the outside of a bolt and that of the hole to be tapped depends first on the theoretical depth of thread; secondly, on the degree of rounding off of that thread at top and bottom, and, thirdly, on the nature of the material to be tapped. Now, taking Whitworth's threads first, I am sorry to see from year to year a big blunder continued in each annual issue of the *Engineering Trades Almanack* by the Nottingham Malleable Iron Company—viz., that the depth of the Whitworth thread is equal to its pitch. The fact being that the thread is rounded off both at top and bottom to an extent equal to 1-6th of the pitch (one-sixth), leaving the total depth of the thread only two-thirds, instead of the whole of the pitch. Mem.: Whitworth's angle of thread is 55°.

Next as to material The copper alloys, such as brass and gunmetal (now fashionably called bronze), and perhaps aluminium bronze, and some others, about which I cannot speak, as I do not know, will admit of tapping with a nearly full thread, as will also wrought iron, if the taps in this last case are in really first-rate order, which means that they have good keen edges to cut with. But cast iron is a very different substance to deal with, and at the same time it varies very materially in quality at different places, or according to mixture at any one foundry.

I hold that no attempt should ever be made to produce in cast iron an internal or "female" thread of full section, or what the workmen call a "full thread," unless it is to be done by cutting out the material entirely in a screw-cutting lathe by means of proper screw tools, commencing, say, with an internal side single pointed tool, and finishing with a female chaser of usual form. And even then I think it is better (as it is much easier, and therefore, if carefully done, is much more likely to be satisfactorily done) to leave the rounded part of 1-6 the depth of the thread totally out of the question, and therefore in cast iron to bore the tapping hole very considerably larger than the theoretical size. If you do not do this, you will find the metal crumble away during the process of tapping, and the hole will not only be as large as it should in the first instance have been bored, but all the inner part of the thread will be ragged, with plenty of lodgment for dirt; and the difficulty of removing that dirt, when you have not a tap of right size at hand, becomes a source of grief when you have scrupulously to clean in order to finally adjust a job.

As to taps of other makers, such as Clements, succeeded by his nephew, Joseph Wilkinson, who, by the bye, actually cut and made all Clements's hobs for him while working as an apprentice, and now in the possession of Elliott Brothers, of Charing-cross, as far as I have gone in examining these, of which I have a great number, including taps, hobs, dies, &c., &c., I think I may say that Clements' angle of thread, which is much less than Whitworth's (already stated as 55°) is, as a rule, 40°; but in different taps, made specially for certain purposes, the amount of rounding off varies considerably. I have specimens of Clements's threads or tools from his hobs, or copies of them, in which the angle is only 35°, or even as low as 30°.

Now, if anybody who has "Holtzapffel's," Vol. II. (and that is just the book that no amateur worthy of the name should be without), he will find it thus written on page 673, viz.: "For a long series of years I. I. Holtzapffel . . . . made, as occasion required, a large or small screw, a coarse or fine, a shallow or deep thread, and so forth . . . . not less than one hundred varieties of all kinds."

Now, anybody who wants these "hundred varieties of all kinds," tabulated with depths of threads, &c., &c., makes about the mildest sort of request, and the least likely to be granted, that ever came under my notice. I have about a hundred sorts and varieties myself, and can pretty well appreciate what would be the labour of making such a table.

By the bye, "mild," when I was at school, meant unlikely to be complied with, or even *absurd*, but is, perhaps, not vernacular, so I give the explanation of what I mean by the term.

Just a word on slides. Many amateurs have a fancy for gunmetal loose sides to slide-rest, and gunmetal nuts to the same, believing, no doubt, that workmen thrust upon them cast-iron ones because they cost less. Now, I believe, I could fit five gunmetal side-pieces in less time than I could two cast-iron ones.

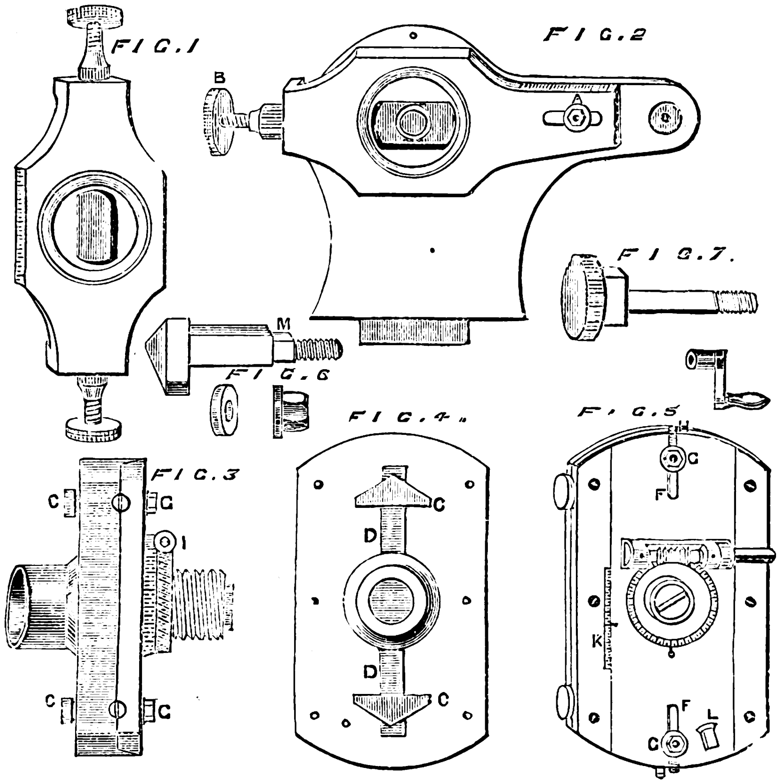
Also, I estimate that every set-screw, or binding-screw, in a 5in. slide-rest costs 1s. 6d. by the time it is fitted into its place, if the work is done as it should be.

Cast-iron nuts are out and out the best for use with cast-steel leading screws, but I should use gunmetal nuts with Bessemer steel screws in second-class rests. Of course, cast-steel screws for best rests run into a good deal more money.

J. K. P.

COMBINED OVAL AND ECCENTRIC CHUCK.

[19833.]—I wish to give a description of how a chuck can be made, which may be used for either oval or eccentric work; and in doing so, I may state that it is only for the use of those who, not being skilful enough to make the separate chucks themselves, and who cannot afford to buy more than one, by getting an oval chuck made after this pattern, can, at the cost of a few pence, use it as an eccentric chuck for all purposes, except for what is called straight-line work, which requires the slide to be moved by a leading screw. The pattern of this chuck is the one given in all books on turning, and I suppose I may call it old-fashioned, as the one described by Mr. Evans in the Mechanic for July 8th, 1881, is a newer pattern, and if I were making another for oval work alone, I should certainly adopt it. I think it would be easier made, as it would avoid having to cut slots; and also there is less strain on the arms which embrace the ring, and which arms would be more readily made parallel, on which parallelism greatly depends the smooth working and truth of the chuck. However, I have made two of the pattern now described, one for myself and one for a friend, and they both work extremely well. The one I made for my friend is not a combination one, I having previously made him an orthodox eccentric chuck. In writing this description, I do not give the minutiæ of the different operations required in the construction, as Mr. Evans has already done so in the number of the Mechanic referred to; at least, as far as the two chucks correspond, and I could not improve on his lesson. Fig. 1 is a view of what is called the eccentric ring, as applied to an ordinary plain lathe-head. Fig. 2 is the pattern which I have adopted in fitting it to my own and friend's back-geared lathes, and the drawing speaks for itself, A, Fig. 2, being a bolt, tapped into lathe-head, which passes through a slot in the ring casting, and when the ring is drawn across the desired amount of eccentricity by the screw B, the conical point of which enters a small hole in the side of lathe-head, A is tightened and secures the ring immovably. Fig. 3 is a side view of chuck, Fig. 4 a back, and Fig. 5 a front one. C C, Figs. 3 and 4, are the jaws which embrace the ring; they slide freely in the slots D D, Fig. 4; they have a shoulder, M, Fig. 6, to bed against the back of slide, and passing through the short slots FF, Fig. 5, are secured by nuts as shown at G G, Figs. 3 and 5; the object of these short slots, which are narrower than the long ones, is that the arms may be adjusted to embrace the ring tightly or not, as may be desired, and they are prevented getting slack during use by the two set-screws shown by the dotted lines at H H, Fig. 5; these are tapped through holes in the ends of the slide, and are nicked for a screwdriver. I, Figs. 3 and 5, shows the division-wheel and tangent-screw worked by the winch-handle J. In making the wheel, as well as all other similar division-wheels which I have fitted to either oval or eccentric chucks, I have adopted 120 divisions as being a better number than 96, generally recommended in books, as in doing double counting the patterns look better when finer than 96 would make them. K, Fig. 5, shows the position of a scale of 1-20in., which is necessary when using the chuck as an eccentric one. When doing so, the eccentric ring is removed from lathe-head, and also the arms which embrace it, shown separate (Fig. 6), with nut and washer. In place of these arms, two bolts, with round flat heads and square shoulders (Fig. 7), fitted nicely to the slots D D, are substituted, and by means of these the slide can be clamped to the body of chuck at any desired degree of eccentricity. These bolts moving in the slots D D allow the slide to be moved as far as necessary. L, Fig. 5, is a steady-pin passing through both slide and back of chuck when "all is at centre," a term which all ornamental turners will understand. This pin, of course, must be removed when the chuck is running as an oval one, or when the slide is thrown out eccentric.



This plan of clamping the slide by the bolts, instead of fixing it by a leading screw as in the usual pattern of eccentric chuck, is sufficiently handy when using it for the only work it is likely to be wanted for—viz., doing geometric figures by double counting, using the eccentric cutter to cut the circles, and in using it this way most beautiful figures, consisting of patterns composed of loops and cusps, may be produced, which can hardly be distinguished from those done by the epicycloidal or geometric chucks. There is, as I have mentioned before, one use of the chuck only which cannot be availed of without a leading screw to move slide, and that is some forms of straight line work which require the slide to be traversed vertically while a drill is cutting the lines. For all plain eccentric patterns can be done much more readily by the eccentric cutter alone, combined with the movements of division-plate of lathe pulley, and the figures now produced by double with eccentric chuck, division-plate of lathe, and eccentric cutter, are what used to be produced by the cumbersome and costly double eccentric chuck now, I believe, obsolete. There is one other use which Mr. Evans says the eccentric chuck is necessary for, and that is the geometric staircase, as shown in his ivory vase in the MECHANIC of March 3rd; but this can be much more easily done, and with far less danger of spoiling either work or chuck, by the universal cutter combined with the movements of division-plate of lathe and slide-rest; and I have done many of them in this way for such purposes as stems of vases and candlesticks. There is an excellent chapter on patterns done by double-counting in Northcott's "Lathes and Turning," and it is the only book I know which treats of this particular branch. I believe it was first introduced by Capt. Ashe, and perhaps he may have written on the subject. In treating of this combination chuck, let it not be imagined that I think it is as good or a better plan than having two separate chucks each for its own use, and I have, as I have said before, made separate ones; but it having struck me how easily they could be combined, I experimented on my oval chuck, and found the combination quite satisfactory.

F. W. G.

HUXLEY'S CALCULATING-MACHINE

[19834.]—In the ENGLISH MECHANIC, Vol. III., No. 59, page 131, will be found a drawing and description of a calculating-machine of my invention. In referring to this, my object is to show the important improvements in the working of the present invention, accomplished by the substitution of motion from centres, instead of a sliding motion as formerly.

The main feature of the machine is, that one scale of divisions being made to cross another, it is contrived that in working the same angle is maintained in the final operation to obtain the answer; so it is evident the readings on the two scales at any point formed by an angle are always in the same proportion to each other. Here, then, is an instrument which answers questions in the rule of three, multiplication, division, &c., and also involution and evolution (by means of a special scale), limited of course by its extent.

It may now be explained that in order to substitute a motion from centres, it is necessary to transfer the former scale, placed on right lines, to the arc of 60° as seen at F and G, Fig. 1, the said right line forming the chord of such arc, and such transfer being made by placing one leg of the compasses in the point A, Fig. 1, and producing the scale on the arc. The points D and E are the two centres from which are produced the arcs A H and A I, on the forearms of which are the scales. Fig. 1 is shown in this position in order that the principles involved in the construction of the machine may be understood. The joints D and E are made in the same manner as the sector or 2ft. rule. At the joint A one arm rotates above the other, thus allowing the forearm G to slide upon the forearm F. Fig. 2 shows the scale produced on an arc from a logarithmic scale on the chord thereof. This scale, if required, might be engraved also under each of the forearms, leaving out the words thereon, being necessary on one side only.

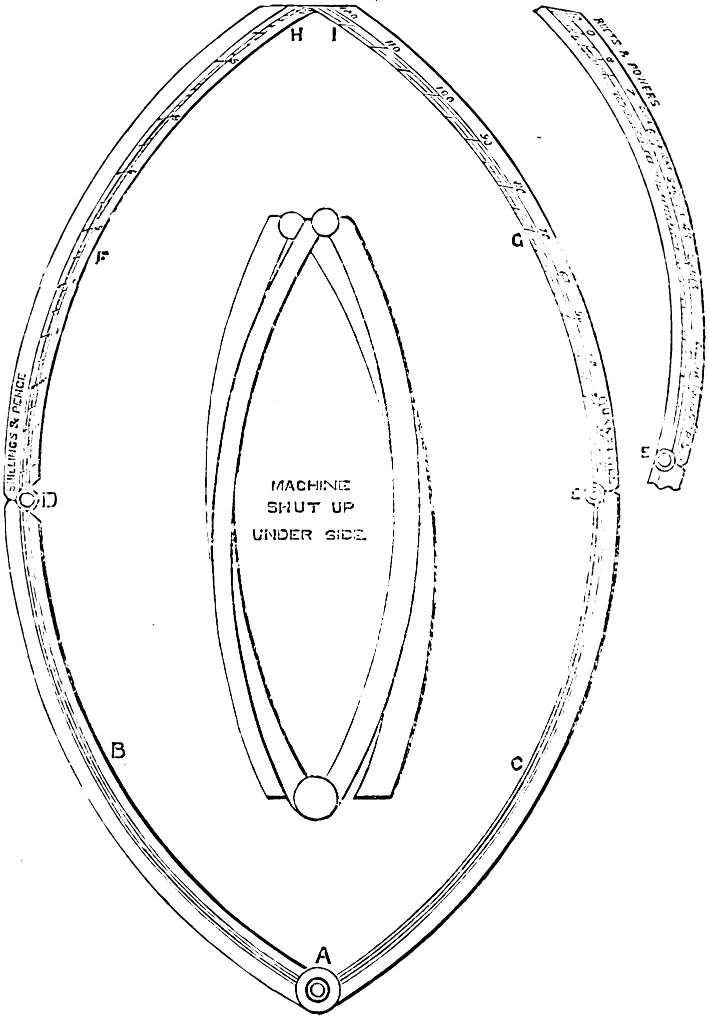


FIG. 1.
FIG. 2

There are two views which may be taken respecting machines of this class; one is theory, the other practice. In theory, that which will work correctly with tens or hundreds, would be equally correct with millions. But practically, our resources are limited by the dimensions which we may deem it convenient to have such a machine for use, and the amount of subdivision of the scales, which we may think advisable to crowd within such space.

Fig. 1 (space being limited) has only half the scales of a machine intended to be made of double that size, namely, 20 shillings in pence, and 240 divisions, portioned into cwts., qrs., and third parts of qrs. (this last amounting to always less than 1d.), total one ton. This is designed specially for use for calculating the workmen's wages in "ironworks," where many calculations have to be made of cwts., qrs., and lbs., at s. d. per ton, and requires a considerable time, if done by slate; but the answers worked out by the machine could be found as fast as they could be written down.

Directions for use.—Any division of any part of either scale may be put in contact with any other, by moving either or both the arms, F and G, on the centres D and E; and now having adjusted a certain quantity to a certain price, and wishing to know the value of some other quantity at such price, we press together or open the arms B, C, till the quantity sought touches upon the opposite scale, where the answer is then seen. The reverse, or new quantities, may be found for given prices. Many other uses could be explained, but space warns me to close.

Barry-road, S.E. J. H. Huxley.

GRINDING AND POLISHING GLASS SPECULA.

[19835.]—IN treating of the Foucault's test. I shall pursue the same plan as I have before—viz., explain the principles, then go to the practical application of them. I shall, as before, suppose we are testing a 6in. speculum of 60in. focus, and that the amateur uses his right eye. This, like the right hand, is, I suppose, mostly used. I shall, therefore, arrange the diagrams and apparatus as most convenient for this mode of applying the test; at the same time, should the amateur be obliged to use his left eye, he can study the principles from the diagrams, and afterwards arrange the apparatus for use in his left-eyed way. I must further observe that the amateur must be able to see distinctly at the distance the speculum is from him when testing; and if he cannot, he must wear spectacles that will enable him, for it is all important that the shadings on the speculum should be within the range of his most distinct vision, or the delicacy of the test will be impaired; as for myself, for instance, I am shortsighted, and I have to wear concave spectacles, or I could not test at all. As I find many amateurs know nothing at all about the Foucault test, I shall, therefore, have to treat of the very rudiments of the process; and I must confess to a feeling of great difficulty in attempting to describe the shadings as appearing in the old way of testing; but, happily for the amateur, the way I now test is free from this difficulty, and, therefore, much easier to describe and to carry out; and as it does not depend on our judgment got by long experience in the use of the test, it can be used at once by the amateur, and in his hands is far more accurate than the old way. But I must first describe the old way as briefly as I can.

In Fig. 1 is given a horizontal section of the important parts of the testing apparatus necessary to the understanding of the principles involved. S is the speculum, which, to save valuable space, I have drawn about one-third its proper focal length as compared with its diameter; but this in no way alters the principles—in fact, the exaggeration rather aids the ocular demonstration of the laws we have to study. C is the chimney of a paraffin-lamp: in my case it is a common ½in. burner or wick; the chimney is a brass tube the same length as the ordinary glass chimney; the flame is seen to be placed obliquely to the speculum so as to have more light than from the flat side of the flame. We must suppose that through the brass chimney there is a very small hole, say about 1-300in. in diameter. How to get this I shall explain when I come to the practical details. This hole must be opposite the brightest part of the flame; the light from the flame will pass through the hole and diverge on to the speculum, which must be at a distance of 120in., i.e., the radius of its curvature, which curvature we will suppose is perfectly spherical. From the speculum the light is reflected back to a point the same distance as the hole in the chimney: this is the focus for the speculum so arranged; but to be able to view this focus, we have to alter the speculum a little, so that the focus is thrown about 1½in. to the left of the hole, and about opposite the middle of the chimney; here we can view it with the right eye at R, the nose will then be at N, and the left eye at L. Now it is evident, if we put the eye close up to the focus, the pupil of the eye will take in all the rays coming from the speculum, as these are all concentrated into the 1-300in., the pupil being ⅛in. or more; now, with the eye thus close, the whole of the face of the speculum will appear equally illuminated (I suppose now it is perfectly spherical); 1, 2, 3 represent the three positions of a piece of sheet-metal seen in section, the right-hand edge of which is a straight edge; this sheet-metal is bent as shown to allow the nose to fall into the curved part without touching it, thus the eye can be got conveniently close to the straight edge. This straight edge we will call, in the future, the shutter, for it has to shut off the light in various positions of the cone of light. Now, it is evident that with the shutter at position 1, if we make it gradually pass from left to right, it will, to the eye close up to it, appear to shut off the light from the left-hand side of the speculum; then the shadow will gradually cross over to the right, while the right-hand edge of the speculum will be the last to disappear. This is easily understood by observing the way the shutter cuts the cone of rays as it passes from left to right. Now, suppose the shutter to be brought back beyond the focus, to position 3: here it is evident that the cone of rays is reversed, and that the shutter, in passing from left to right, will first cut off the rays coming from the right-hand edge of the speculum, and as the shutter advances, it will appear to move on the speculum from right to left—just the opposite direction of position 1; so by this means, and this is the first lesson the amateur has to learn, he can tell whether the shutter is before or behind the focus. If it shuts the light off from the left—*i.e.*, the point from which the shutter is moving, then the shutter is before the focus; but if the light is shut off from right to left—*i.e.*, in the opposite direction to which the shutter is moving, then the shutter is behind the focus. Now let the shutter be placed as in position 2—that is, right opposite the focus; here it is evident that the shutter will cut off all the rays at the same time—*i.e.*, right and left, and middle rays, and the shutter will not appear to pass over the speculum, either from the right or the left-hand side; but a shade, or decrease of light, will come on equally well all over the face of the speculum. Now, in all cases, we can find this exact point by a little experimenting. If the shade is darker on the left side than on the right side, it is evident the shutter is a little in front of the focus; move it back a little, say the 1-50in., and now pass it gently from left to right as before. But now we will suppose the amateur sees the shading on the right is a little darker than that on the left, as the shutter is moved from left to right. This tells him that it is a little behind the focus, and that, therefore, he has moved it too far back: he puts its forward about 1-100in., and again passes it from left to right. Now he cannot tell which side is darkening the most, the right or left of the speculum; and now he knows he has got the exact focus, because the whole of the face of the speculum darkened equally until the light went out as the shutter finally cut off the last ray. Now, if the amateur puts this speculum in a telescope, and finds out the focus of the various zones from observation on a celestial object, he will find that the centre rays, say of 2in. diameter, are longer than the outside rays, and in reality that there is no focus for the whole of the speculum, each zone having its own focus at a different distance from the speculum to every other zone, and that, therefore, perfect definition is not to be expected from a spherical speculum. The rule by which he can calculate this spherical aberration, *i.e.*, the aberration of a spherical surface for parallel rays is: Divide the square of the semidiameter of the speculum by four times the radius of curvature. In our supposed case the aberration would be ·019 nearly, *i.e.*, the centre rays would be ·019 (nearly 1-50in.) longer than the outside ray. From this it is evident that to bring parallel rays to a focus, the centre of the speculum needs to be deepened so as to shorten the focus of the centre rays, or the focus of the outside rays may be lengthened by the outside of the speculum being flattened. In other words, it must be made parabolical. I may just observe that in thus shortening the centre rays, or lengthening the outside rays, we first pass from the spherical surface to the elliptical, and from that to the parabolical; and, if carried further, we get the hyperbola. And I must further observe that these shade out of one into the other quite imperceptibly, and it is the most difficult point to decide when the parabola is just reached, not falling short of it, and being only an elongated ellipse, nor going beyond it, and being an hyperbola, it is impossible to tell as exactly, by the old mode of judging by the shadings (and it requires a vast amount of experience to tell), when the parabola is reached as by the mode I hope to describe in my next letter. Of course, I am supposing that the general truth of each figure we are supposed to be testing is kept—i.e., that the zones between the outside and centre are truly part of the curve supposed, as well as the outside and centre. This is of no less importance to good definition than the centre and outside rays coinciding in their foci. As the centre rays of a spherical surface require to be shortened to bring them to the same focus for parallel rays, it follows that when an elliptical or parabolic, or hyperbolical surface is tested by the Foucault's test, that the centre ray is shorter than the outside ray in its focus. Now it is impossible to tell by the mere shadings when the perfect parabola has been reached, or when the perfect parabola has been lost, and the hyperbola begins; by long practice an approach to certainty may be attained; but it is utterly impossible to describe to an amateur the appearance of the parabola, so that he can be certain, without a deal of practice, the very thing he has not got for his first speculum, and wood engravings are far too coarse to give any proper idea of the very delicate shadings that indicate the true figure; it would not do to tell an amateur that he must wait till he has got as much practice as a With or a Calver before he can judge correctly of the figure of his speculum. This made me desire to find out some easy and yet certain mode of testing for the amateur's use. Now, just to show the difficulty of the old mode, let the amateur remember that in the spherical surface there are but three possible positions for the shutter, therefore the testing for the sphere is most simple; but when we come to the parabola, where there are no two zones with the same focus, when tested by the Foucault's test, the variety of shadings is immense, and is according to the position of the shutter. To show this let the amateur study Fig. 2, where he will see that there are at least eight different places where the passage of the shutter would give different shadings, even though we only divide the speculum into two zones, but it may be divided into four or five zones; the shutter passing over the focus of each would give a different shading for the whole face; now Fig. 2 will help us to study this with two zones taken into consideration (I omit the lamp and diverging rays); now with the shutter at position 1, passing over the cone, it is evident that because it is within the focus of the centre rays B C, that it would appear to pass over from left to right without any shading, since the shutter would first cut off the A, then B, then C, and finally D in the order they occur, *i.e.*, from left to right; at position 2 the left edge of the speculum would be darkened first, then, when the shutter got to the focus of the ray B C, these together would be suddenly cut off, *i.e.*, left and right side at once, and the shadow would then advance to the right side of the speculum; at position 3 the left side of the speculum would be darkened first, then, when the shutter reached the ray C, the place C on the speculum would be darkened, leaving the spaces B and D still light, the shade would creep from C to B, and from C to D, till last the right-hand of the speculum would be darkened; in position 4 the light would be cut off from the space A and C together, then the shading would creep from C towards B and D, and from A towards B, while B and D would be the last to be cut off; in position 5, *i.e.*, at the focus of the outside zone, the ray and space C would be first to be shaded, then the outside A and D would follow, and be shaded together, and the last part, where the light would linger, would be at B, because this is the ray that is furthest from the shutter when it started to move from left to right, and therefore the last to be cut off. I need not go through the other positions, 6, 7, and 8, of the shutter, as my object is not to recommend the amateur to attempt to master this almost hopeless mode of testing, by observing the shadings in the many positions of the shutter that it is capable of being put in, to give variable shadings, even with a parabolical speculum, and then he ought to have a perfect speculum to learn from. His own may be, and probably will be at first, anything but a perfect parabola: how then can he learn with the means at his hands? At one time I thought it was almost hopeless to attempt to teach amateurs the use of the test by description only; but my first step in this direction was when it struck me that if the amateur could always start his testings of his speculum from one point in the cone, and always compare the indications with one another at this point, he would do away with seven of the positions that the shutter may assume, and thus his perplexity would be greatly reduced. I should, therefore, recommend him always to put his shutter at the focus of the outer zone, because the rays crossing here at the greatest angle, this point could be more certainly determined than the focus of any smaller zone. Now, to find this focus let him put, by suspending by a string, a circular disc of cardboard 5in. diameter on the centre of his speculum, thus leaving a zone ½in. all round. He must then find, by experiment, the position of the shutter where the left and right-hand part of the zone are shaded in exactly the same degree, as the shutter is passing over the rays. He can then take away the cardboard disc and pass the shutter over the rays coming from all parts of the speculum. He must be careful not to shift the shutter backwards or forwards, only from left to right. He must now observe how the face of the speculum is shaded, and see if it is as described when the shutter is at position 5; but how to enable him to distinguish an ellipse from a parabola, or the hyperbola from a parabola, I know not by mere description—the

FIG. 1.

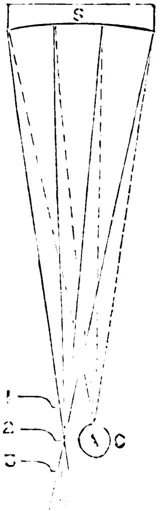

FIG. 2

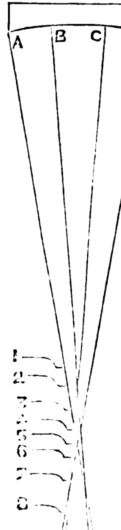


shadings are so delicate that distinguish the one from the other. Now, the only direction I could give the amateur for a long time was, that he must test by zones in his telescope on a celestial object, and when he has thus got all his zones to give the same focus for parallel rays, he is not far out. He can then observe how the shadings come on under the Foucault's test, and this test could then only give him an idea of the general truth of the figure he had got, and not when it was the exact parabola; only after long practice he may aproximately judge from the shadings. I was not satisfied with this evidently-imperfect state of things, and one requiring a great deal of trouble to the amateur in having to go through two testings, and often having to wait long for a fine night. I know there is another way used by Mr. Calver, if I rightly understand his description in his new edition of "Hints," 1877, page 8, and the way he corrected his 37in. speculum for Mr. Common. I hope I shall be corrected if I misunderstood Mr. Calver's description, but this way is as much trouble as the one I have above described. Mr. Calver's mode seems to be this: he evidently gets the speculum, by his extensive knowledge of the practical working and the shading of specula, as near as he can to a sphere, by testing at the centre of curvature (co-called) or beyond that to the ellipse; he then removes his artificial star, say, to 50 yards distance, and then he works the speculum so that the shading comes on all over alike, and in this way forming an ellipse, which is an approach to the parobola from the sphere; he then puts his artificial star, say, 500 yards distance, and works again in the same direction as before, until he gets again the whole of the shadings to come on all over the face of the speculum alike. This, then, is an ellipse of greater eccentricity than the former, and nearer to the parabola; he then, perhaps, removes his artificial star to a still greater distance, if convenient, and again works his speculum to this test, which is a still nearer approach to the parabola; but, of course, rays proceeding, say, from 1,000 yards are not parallel. He has now to judge how much more working in the same direction and manner will convert this elliptical speculum into a parabolical one. Here, of course, his extensive experience aids him; but where is the poor amateur in his attempts without all this experience? Why, it is almost as good as impossible to him for his first speculum, for this mode demands a great deal of practice and means; and I felt dissatisfied with the state the Foucault's test came into the hands of the amateur, and I could not rest till I discovered an easier mode, and yet a strictly accurate one, for the amateur's use; but as my letter has reached its usual length, and as I think I have given the amateur enough to master at once, I must defer till my next my mode of ascertaining what the figure is of his speculum, and whether it is a true parabola or only an ellipse or hyperbola. I hope to give the description of the apparatus necessary to the practical carrying it out also in my next. There may need even a third letter on the subject, a gathering up the scraps, and giving warnings against sources of error or failures in the practical carrying out of the test. It may be that someone else has before used this form of the test, but I have never heard of it or seen it described.

A mistake has crept into my last letter, page 569, second paragraph, line 33, the word "polisher" ought to be "speculum."

Will Mr. Brashear, to whom I tender my most sincere thanks for his excellent letter, page 592, Vol. XXXIV., explain to me and others what he means in the second paragraph, lines 5 and 6, by "If the tint, which should be of the first or second order," what is "the first or second order"?

H. A. Wassell.

Addenbrook Villa, Love Lane, Stourbridge.

OSSIFEROUS OR BONE-CAVES—PART II.

[19836.]—In a previous paper on this subject we dwelt on historic and pre-historic caves; it will therefore be necessary to confine our remarks to-day to Pleistocene caves, or those belonging to the Palæolithic or age of Unpolished Stone. The European fauna of this age is found to differ from that of the pre-historic, and to include the cave-bear (Ursus spelæus), cave-hyæna (Hyæna spelæa), cave-lion (Felis spelæa), mammoth (Elephas primigenius), glutton, musk-sheep, bison, lynx, reindeer, wild horse, hairy rhinoceros (R. tichorhinus), R. leptorhinus, R. hemitæchus, Irish elk (Megaceros Hibernicus), &c., whilst in no single instance have the remains of any domestic animal been found. There are a great number of caves belonging to this age. Some of the most celebrated are Wookey hole, Kent's cavern, Brixham cave, Kirkdale cave, the cave of Kühlock, the caves of Périgord, Dream cave, and the caves of Belgium.

At a very early date Dr. Schmerling pursued his explorations in the neighbourhood of Liége, where there are numerous caverns, the floors of many of which were composed of unbroken stalagmite. In the cave earth below he not only found the bones of animals both extinct and recent, but also traces of man in the form of rude flint implements, and in the cave of Chokier of a polished and jointed needle-shaped bone with a hole pierced obliquely through its base. In a few cases he also found skulls, teeth, and other human bones. Careful explorations of these Belgian caves were further pursued by Mons. E. Dupont, and as many as 30,000 unpolished flint implements have been found in the cavern of Chaleux and 1,200 in those of Furfooz.

The celebrated Kent's cavern was first scientifically explored by the Rev. J. McEnery, a Roman Catholic clergyman. He commenced his researches in 1824; but when he announced the result in 1825 he found it received with scepticism and incredulity. Later, in the year 1865, the investigation of this cave was pursued under the auspices of a committee appointed by the British Association. Very numerous and most interesting are the fossils and relics which have been discovered. They vary considerably, according to the different strata in which they lay embedded. On the surface was found a miscellaneous collection of articles which would suggest its having been frequented during the historic period. They consisted of pebbles of various kinds, Roman pottery, bronze articles, spindle whorls, bone awls, chisels, combs, &c. In the modern stalagmite the objects included chiefly charred wood, remains of extinct mammalia, flint implements, &c., whilst the antiquity of man received fresh corroboration from the fact of a human jaw being found at the base, whilst the bones of extinct mammals were found in the upper part. Below this stalagmite was the cave-earth, which yielded upwards of 350 flint implements and flakes, besides a quantity of charred bones and charred wood, indicating the places of the hearths; remains of cave-hyæna, Machairodus latidens, mammoth, rhinoceros, Irish elk, and other animals. Also bone tools, consisting of harpoons, some barbed on one side and others on both, and part of a needle, the eye still distinctly visible and capable of admitting fine twine, also a bone pin, &c. The bone needle closely resembles one that was found in one of the French caves. The breccia below contained even more bones than the cave-earth, and without exception they belong to the cave-bear (Ursus spelæus). Mingled with them were four flint implements, one being perfectly angular and sharp, thus proving man to have co-existed with these carnivora. It is besides evident, from the presence of the charred bones and wood in the cave-earth that man must have made the cave his home, where he cooked and ate his meals; the fires being also necessary in order to chase away wild animals. That this cave was also the dwelling-place of hyænas is proved by its possessing those characteristics which are common to all hyæna dens, viz., by the bones which are always gnawed and split for their marrow, by the corners of the entrances being rounded by the friction of the passage of these animals, and by the bones on the floor being worn smooth by the feet of the hyænas. As it was not possible that man shared the occupation of this cave *with* the hyæna, we are led to infer they occupied it *alternately*, the hyæna taking possession while man went on his migrations to other caves, to be disloged on his return. Even in the present day, the same thing is related by the Rev. Dr. Tristram to take place in the caves of Tunis and Syria.

It was in Nov., 1857, that Brixham Cave, in the little fishing-village of the same name, near Torquay, was accidentally discovered by the loss of one of the men's implements whilst quarrying the limestone rocks. The tool was seen a few days later at the bottom of a hole large enough to admit a man. Mr. Philp, who had recently purchased the property, at once descended in order to recover the lost implement, and found that it led into a large cavern, with a stalagmitic floor, from which numerous bones were seen projecting. In May, 1858, the Geological Society appointed Dr. Falconer, Sir Chas. Lyell, Sir A. C. Ramsay, and others, to make a thorough investigation, and decide the question which had been raised by the researches in Kent's Hole, as to the contemporaneousness of man with the extinct mammalia Grants of money were obtained from the Baroness Burdett Coutts and the Royal Society. The result of this exploration proved the cave to have been the dwelling-place of reindeer, mammoth, and other extinct mammals, their bones being discovered in the various deposits. Although no human bones have as yet been found, still, beneath the stalagmitic floor and in the gravel below, were obtained 30 stone implements and flakes, whence it is inferred that man was in Devonshire a contemporary of those animals whose remains are found commingled with these traces of human industry. Thus the alleged discoveries in Kent's Hole received a full confirmation; and it was decisively proved that man not only lived prior to the extinction of these cave animals, but also at a time so remote that the valleys of the district were at least one hundred feet less deep than they are at present.

Wookey Hole, near Wells, in the Mendips, is an instance of a watery cavern, and affords a passage for the course of the R. Axe. It was discovered accidentally by some workmen. Numerous fossil remains of hyenas and their prey, amongst which are to be found even the lion and bear, have been unburied. Dr. Buckland, remarking the peculiar method in which these bones are gnawed, and which is observable in all the caves which these bone-eating animals have made their dens, submitted various bones to hyenas in the Zoological Gardens, as well as to a Cape hyena in Wombwell's menagerie. On comparing the remains with the fossil bones, they were found to bear a remarkable similitude, even to the places of the tooth-marks. Thus, any doubt which might have existed as to this and other caves having been inhabited by hyenas, was at once dispelled. Implements of Palæolithic man have also been found in this cave. As the whole is confusedly mixed together, the cave must have been flooded.

Kirkdale Cave, in Yorkshire, is another instance of a celebrated hyæna den; Dr. Buckland estimating the remains as belonging to between 200 and 300 individuals of all ages.

The cave of Kühloch, in Germany, is supposed to have been inhabited by the cave-bear. It is very interesting, and differs much from other caves. Dr. Buckland, writing of it, remarks, "there are hundreds of cartloads of black animal dust entirely covering the whole floor, to a depth which must average at least ten feet... many hundred—I may say thousand—individuals must have contributed their remains to make up this appalling mass of the dust of death."

Some particularly interesting caves occur in the Dordogne, ten of which have been explored by MM. Lartet and Christy. Thousands of unpolished flint implements have been found, as well as remains of extinct mammals.

Additional evidence of the traces of man in Palæolithic times was furnished by Dr. Falconer, F.G.S., in 1859, by the results of his examination of some of the ossiferous caves of Sicily. The Grotto di Maccagnone was especially noteworthy, as it bore marks of having undergone several changes owing to various climatic influences. Also it gave grounds for inferring that the physical condition of the country was different then from now. For in the breccia, besides ashes and flint implements indicating the presence of man, he found also bones of hyæna and other animals, and especially a vast number of those belonging to the hippopotamus.

We have frequently had occasion to mention the unpolished flint implements; it would therefore, perhaps, be well to briefly describe some of them. They are of very various shapes, sometimes mere flint chips, at others of an ovoid, lanceolate, triangular form or canoe-shaped, and from two to eight inches in length. They consist chiefly of awls, hatchets, saws, round stones used as hammers, spears, javelins, arrow-heads, cutters, scrapers, and lance-heads. Some of them are devoid of handles, others have their ends chipped off for their insertion. The Palæolithic bone implements comprise bone needles, supposed to have been used for sewing skins together. There are also awls and various others to which it is difficult to assign any use. Many of these Palæolithic implements are rude and curious works of art. Thus in one instance a poniard was found cut out of a reindeer's horn, and it was ingeniously made to represent a reindeer, the hind legs being stretched out to form the blade, the back of the animal forming an even surface for a handle. On a piece of mammoth tusk was found a representation of that animal with its long hair. Various other designs have been met with—one of a reindeer, another of two horses' heads, a human figure and a snake, another the well-defined outlines of an ox, another of two outlines of fishes; also parts of an ibex, figures of horse, rhinoceros, Irish elk, &c. And, considering the tools with which these artists did their work, it is matter of no little surprise that these designs, which really display no small amount of artistic feeling, should have been so well executed. And this, moreover, as they are proved to belong to the Palæolithic age, when man was probably simply a hunter, and without the slightest knowledge of metallurgy or pottery.

Having briefly spoken of some of the chief of these Palæolithic caves, the only question which remains to be answered is—what have we learnt from them? In the first place, then, they prove very convincingly that man was coeval with the extinct mammalia, thus assigning to him an antiquity very much more remote than was believed previous to cave exploration, but which is now held by most of, if not all, our eminent scientific men, including Lyell, Ramsay, Huxley, Dawkins, Lubbock, Buckland, Murchison, and others. Then, helped by the data furnished by these caves, and aided by our imaginations, we can form a very vivid and accurate picture of the kind of life led by these distant ancestors of ours. We have seen how, in their uncivilised condition, they contrived to live without houses, making their homes in rude caves, the dens of wild animals

when vacated by man. We have been able to find out the amusements which helped to while away their leisure hours. How, when debarred by inclement weather or other causes from enjoying the pleasures of the hunting-field, they occupied themselves by exercising the artistic talent which lay dormant in them, by adorning their rudely-made implements with roughly carved designs. And, further, we are assisted in forming some conjectures as to what race of people these Palæolithic men were. From the similitude of their engravings on stone and wood, both in design and style of workmanship, to those of the Eskimos of North America of to-day, as well as the fact that, like Pleistocene man, the Eskimos disregard burial and live on the same kind of food as Palæolithic man, Mr. Dawkins holds that in these Americans the same ancient race still survives. He considers that the many points of ethnological resemblance which they have in common cannot be the result of mere accident, but that they are most probably blood-relations.

Again, we have gathered from the examination of these caves much knowledge concerning the European fauna. A comparison of the fossil remains in the caves of the Continent with those of Great Britain proves the fauna to have been similar. We have seen how numerous and varied have been the remains, which are estimated as having belonged to over forty different species, ten of which are believed now to be wholly extinct.

And besides all this, how much have we learnt respecting the climate of Europe and the alterations in its physical geography.

> "There rolls the deep where grew the tree,
> O, Earth, what changes hast thou seen!
> There where the long street roars, hath been
> The stillness of the central sea.
>
> "The hills are shadows, and they flow
> From form to form, and nothing stands;
> They melt like mist, the solid lands,
> Like clouds they shape themselves and go."

That the climate of Europe was very different in the Pleistocene age from what it is at present is judged more especially from the fauna then inhabiting Europe. Thus we find remains of animals accustomed to Arctic regions, such as the rein-deer, woolly rhinoceros, ibex, and mammoth. It is true that the last-mentioned is supposed to have possessed a somewhat elastic constitution; still, it is believed to have preferred cold climates because remains are found most abundantly in the extreme north, many skeletons, and in one instance an entire body preserved in the frozen soil, having been obtained in Siberia. At the same time, traces of animals which now only inhabit temperate zones have been found in these European caves, such as the lion, hippopotamus, and hyæna. This has led geologists to believe that the winter was more severe and the summer milder, and that these animals migrated from N. to S., and S. to N., according to the changing seasons.

This alteration in the climate of Europe is thought to be largely due to the changes which have taken place in its physical geography. From the evidence derived from the fossil remains, not only of these caves, but of those yielded by rivers, and by means of different soundings, geologists argue that in the Pleistocene age, Caldy Island must have been joined to the mainland, and that the Bristol Channel was a fertile plain. That Ireland was joined to Great Britain and Great Britain to the Continent. That the Mediterranean Sea was divided into two salt lakes by Gibraltar being connected to Spain and Africa, and Sicily and Malta to Italy and Africa. That Cyprus was united to Asia Minor; Corsica and Sardinia to Italy; Majorca and Minorca to Spain; that glaciers covered the peaks of the higher mountains of Asia Minor and North Africa; besides other changes. As these physical alterations presuppose an immense lapse of time, geologists are inclined to believe man to be pre-glacial.

In conclusion, whilst these bone-caves have told us so much concerning the climate, physical geography, and fauna of Europe, as well as the antiquity of man, yet they leave us still unenlighted as to his origin, and the truth or falsehood of the theory of evolution. There is no proof that the men whose fossil remains have been found in caves were intellectually inferior to the lowest savage races. No remains of apes, bordering on the human have as yet been met with. But there remains a large field for further exploration, and new discoveries in Greece, Palestine, and other parts of Asia. It will take years to complete, but it is a work which offers many attractions, combining, as it has been remarked, "The excitement of mountaineering with something of its dangers."

M. Sterndale Acworth.

AUTOMATIC MUSICAL INSTRUMENTS.

[19837.]—NOTICING on page 12 the letter of "Gray's Inn" on this subject, as well as one or two others that have recently appeared, I think I may as well make a few comments thereon. The first instrument in which the principle of producing a tune by the use of perforated paper was applied seems to have been patented in 1848. In this case, the notes were those of the ordinary organ-pipes. In 1851 there was standing in the corner of a room at the Society of Arts a fairly large instrument of this kind, and, for all I know, it may stand there still.

The great defect of this plan is that as the paper necessarily travels slowly, the holes open and close *gradually*, whereby a dismal, drawling, moaning effect is produced. I was informed by the late Mr. Croger that he knew of considerable sums having been spent in the endeavour to cure this, but in vain. Somewhere about 25 years ago I turned my attention to the subject, and made several attempts, which were likewise failures, till the idea struck me to employ *free reeds* instead of pipes. I made a model (still in existence) on this plan, using two octaves of concertina notes. This was a vast improvement on the pipes, and I, therefore, claim to have been the first to apply the combination of *reeds* with the perforated paper. The perforated paper was advanced by rollers with indiarubber rings to produce adhesion. A difficulty was, however, found to occur, which I have observed is also apt to occur with the orguinette—viz., the tendency of the band of paper to travel obliquely, and get crumpled and damaged at the edges. This led me to try a pair of toothed wheels, the teeth entering perforations at each side of the band of paper. Another plan which I commenced, but did not completely carry, out was the use of electro-magnets to open ordinary pallets, the paper passing over a metallic drum with a row of contact springs to drop through the perforated paper. A modification of this was the use of metal sheets instead of paper, with strokes and dots of a nonconducting varnish, or of conducting strokes on a non-conducting material. The nuisance of the battery, and the liability to failure at the contacts, are, however, serious drawbacks to this arrangement. The plan has since been employed on a large scale for a so-called electrical organ at the Polytechnic.

Another idea has been to use the perforated paper to admit air to small bellows whose inflation acted on the pallets in an organ windchest of the usual pattern. I found, however, on working it out, that the arrangement became complex and unsatisfactory. This method appears, from your columns, to have been recently applied to act on the notes of an ordinary keyboard, and from the description there is evidently much ingenuity shown in the details. Next we come to the plan of using springs or levers which, on the passage of the perforations, are set free to act on pallets. This I tried on a small pipe organ, but found it very difficult to avoid irregular action, as the adjustment has to be somewhat delicate. I believe, however, the organette (not orguinette) is thus constructed, but with reeds instead of pipes, and I hope any possessor of one of them will state whether the difficulty of adjustment is found to also exist in this instrument. Lastly we come to the orguinette, which is having such a success. In this the novelty consists entirely in the suction principle, and it has very great advantages in some ways. For instance, the paper being pressed down by the air, is kept in close contact with the perforated bar without any system of springs or upper bars. The friction is thus reduced, and the tendency to leakage is almost entirely avoided. There is, however, still the tendency of the paper before-mentioned to get slewed to one side or the other, a defect but partly remedied by the use of the "attachment." I hope this account of an apparatus to which the writer has given much attention, may prove of interest.

A. S. L.

THE ETHER LIMELIGHT.

[19838.]—MR. FISHER, of Tunbridge Wells, has lent me, for experimental trial, his "Ethoxo" apparatus, which has already been mentioned in these columns several times, and I think a short statement about it may not only be of interest, but, to some, of real importance, inasmuch as the apparatus places the very highest form of lime-light, with only one (oxygen) bag, within the reach of country operators, quite out of the way of gas.

I am not sure who was the original inventor of the process of using gas from ether in a lantern. A friend tells me he believes it was first done about three years ago, by Mr. Broughton, a dentist at Manchester, who simply bubbled the oxygen through the fluid, and used for the jet a long safety packing of granulated pumice-stone. The latter was said to give safety, but I should doubt this. The same was said of various packings with the oxy-hydrogen jet; but they all failed at one time or other, and ultimately it was found best to abandon them all, and to trust for safety to good pressure and avoidance of mixture. I should suspect it would, sooner or later, have proved the same here. But, however this may be, the object of the "Ethoxo" arrangement of generator is to greatly lengthen the course by which a small quantity of oxygen may pass through the ether. It is never less than 12in., which gives much hydrogen with so little oxygen as to be safe.

The arrangement is very simple. The oxygen under, say, 112lb. for a 36in. by 24in. by 24in. bag is connected by a T-joint, with a small copper generator. One other branch of the T goes to the ether in the generator, through which a few bubbles pass, carrying off copious ether vapour; the third branch of the T goes to the oxygen-tap of the lantern. The ether vapour goes to the hydrogen-tap, and when turned on alone burns like ordinary gas. The generator is filled with five-eighths of a pint of methylated ether, of which about one-quarter of a pint will be used in two hours. The residue is best poured back after use.

As to the results, the light is, at least, 15 to 20 per cent. better than I can get with the same pressure, with the same mixed jet, and house-gas in another bag. I can only attribute this to the ether vapour being a definite chemical compound, free from the inert and injurious substances which injure common gas. In some localities, the gas itself may do better than it does in London: but with me the difference was very marked, the light being more intense and white. With the polariscope a fine crystal of Brookite, which was a comparative failure with the mixed gases owing to its red colour and the wide angle and peculiar dispersion of its axes, came out very satisfactorily upon the screen when the hydrogen-bag was cut off and connection made with the ether-gas. Students will know what a difficult crystal this is to project, and it is a severe test for any light.

Of course, there is something to be said on both sides. I can see no danger with the apparatus with proper caution, and one is very necessary. Ether vapourises at such a low temperature that there is almost always some little pressure in the generator when filled. Now, if the oxygen-bag tap were turned on *first* when connection is made, a little liquid ether might be forced back into the oxygen tube, or even bag, and if so, a serious explosion might occur. This must be avoided by rigorously turning on the ether-gas tap to the lantern first to relieve the pressure. Again, ether is a ticklish thing to keep in store anyhow, unless one has a cool cellar, which I unfortunately have not, and equally ticklish to carry about. Lastly, ether is such a searching solvent that no grease can be kept upon any taps; hence, however well they are ground, it must be difficult to prevent more or less leakage ere long, when there must be a smell, which most people strongly object to. If I had the apparatus in use I should be inclined to keep it in a tub of water, which ought to stop any smell in the room. Otherwise, it is very difficult to stop it, and this seems to me the greatest drawback.

On the other hand, these objections will apply least just where the convenience of such apparatus will be greatest. To be able, in a country hall, where there is no gas, or in other halls where gas is difficult to get at to fill a bag, to set down anywhere the single oxygen-bag and pressure-board, and a copper vessel no larger than a small tea-kettle, and there and then have at command the most intense form of lime-light with the mixed jet, will be an advantage understood by many. This is what is afforded by the "Ethoxo" form of generator for the ether lime-light. People who have gas will probably not care to meddle needlessly with a highly volatile fluid; but those who have not will probably be exceedingly glad of the information.

Lewis Wright.

OUTDOOR PHOTOGRAPHY AND DRY PLATES.

[19839.]—WE are looking forward during the coming Easter time to employ the extra leisure we shall have in taking a few views direct from nature. Having little experience in such operations, or, in fact, but little experience at all with regard to photography, we are somewhat anxious as to the best manner of proceeding and what materials to employ. If some kind and, more particularly, experienced friend will give a few practical suggestions by which we may accomplish our end without being too lavish as regards expenditure of money, we shall be really grateful. We would like especially to know about dry plates, with some simple formula for developing.

P. and B.

CHEAP DARK SLIDES.

[19840.]—THOSE readers of the "E. M." who, by studying Mr. Stephens letter on page 10 may be tempted to try these cheap and easily-constructed photo-slides he recommends, are likely to be greatly disappointed in their efficiency if their plates be extra-sensitive gelatine, for these thin pine boards (1-10in. thick) are quite permeable to light. I tried them for the purpose recommended, and soon discovered their faultiness. Then I tried blacking them with ink, rubbing in black varnish, soaking in red or yellow dyestuff, but finally concluded that for the shutter we ought certainly use thin Spanish mahogany; the other portions of

the slide may be advantageously constructed as advised; still, as an amateur possessed of experience and not without constructive skill, I can advise my friends in the "E. M." to be content with making their cameras and tripods, but the dark slide, like the lens, ought to be left to the optician; it is a difficult job to make a double slide as it ought to be made, and the price is not so formidable. I got mine from Messrs. Lancaster, of Birmingham, for 5s.; it is extremely well made ¼ plate, and efficient with the most sensitive plates procurable.

E. B. Fennessy.

SCREW PROPELLERS.

[19841.]—To revert back to the subject of inclined propellers, I do not see the advantage of such mode of propulsion, inasmuch as I do not see how you are to reverse them, and go astern. As to "White Swallow's" propeller, I have seen it, and he has, in my presence, submitted it to authorities in London capable of giving an opinion upon its merits. They declare the motion quite novel. It enters and leaves the water in a perpendicular position, having given the water a back-thrust between whiles. My advice to him is "to put it into operation in a moderate-sized boat," and then let the world know its results. I am of opinion it will supersede both the screw and paddle. Its parts are easy of repair and adjustment at sea in moderate weather. It can be fitted on either side of the ship, or on either quarter or stern; it will do away with the long shaft, a deal of friction, and you will consequently get more of the engine-power developed.

To get an efficient scull propeller, you must have it forked like a fish's tail, and, I suspect, flexible; it could be worked with a crank-motion. I notice the swifter the fish, the more forked its tail. It is a mode of propulsion I thought of in 1860, but gave up the idea, as I imagined it would bring great stress on the vessel's stern, and, as I said before, you *cannot go astern with it.*

James D. Curtis,

Twickenham. Captain, R.N.

FUEL AND COMBUSTION.

[19842.]—There are two queries in our last volume relating to fuel and combustion which have passed into the column of "Unanswered," namely, 45349, p. 290, and 45892, p. 506. As these queries involve principles much required in the heating, lighting, and ventilating of rooms and public halls, as also in dealing with questions relating to fuel and combustion, regenerative furnaces, &c., I have constructed a few equations which will perhaps be found of use by your querists. I have not worked out either of the particular problems cited, but have given the general principles by which these and all such others may be calculated.

The temperature of a gaseous mixture is, as is well known, the excess of temperature which will be acquired by the gaseous products of combustion if they preserve the totality of heat disengaged in the reaction. Thus, let H equal the quantity of heat, and h the specific heat by weight of the products, and we have $T = H / h$, a valuating formula which is applicable in all cases where two gases burn in their respective atomic proportions, and based, of course, upon the assumption that the specific heat is not alterable, but constant at all temperatures.

Before proceeding with the calculations, it is necessary to tabulate the total calorific energy of the several combustibles with which we have to deal.

Name.	By weight.		Density (H = 1)		By volume.
Carbon	8,080 C.		——		——
Hydrogen	34,462 C.	×	1	=	34,462 C.
Carbonic oxide	2,403 C.	×	14	=	33,642 C.
Marsh-gas	13,063 C.	×	8	=	104,504 C.
Olefiant gas	11,858 C.	×	14	=	166,012 C.

And first, we shall investigate the calorific power of the elements, carbon and hydrogen, under various conditions, beginning with that of carbon burning in oxygen. Thus, 12 parts by weight of carbon unite with 32 parts of oxygen, and produce 44 parts of carbonic anhydride, with the development of 12×8080 units of heat. The specific heat of carbonic anhydride to water is in the ratio $\cdot 2164 : 1$, and we find, therefore, that the calorific *intensity* of carbon burning in *pure* oxygen to be equal to $12 \times 8080 / 44 \times \cdot 2164 = 10{,}175$ C. This equation may be condensed, and stated thus: the carbon consumed to the carbonic anhydride produced is as $1 : 3{\cdot}67$; therefore, the heat communicated to the carbonic anhydride at the moment of combustion is found by dividing the number of heat units by the quantity of heat necessary to raise the temperature of the carbonic anhydride one degree—$8080 / 3{\cdot}76 \times \cdot 2164 = 8080 / \cdot 794 = 10{,}175$ C.—and if the amount of heat energy were absorbed in a quantity of water equal to the weight of the carbonic anhydride produced, it would raise the temperature to about 2202° C., thus—

Temperature.		Weight of water.		Weight of water.	Temp.
2202°	×	3·67	=	8080	1.

In the foregoing calculation, we have assumed the combustion to have taken place in *pure oxygen*, and in just sufficient quantity to effect complete oxidation; but in ordinary circumstances, the combustion of fuel and gas is made in air: the composition of air being—

	By Weight.	Ratio.	By volume.	Ratio.
Oxygen ..	23·27	1	20·97	1
Nitrogen..	76·73	3·29	79·03	3·76

Now, when combustion takes place in air, an enormous amount of thermal effect is destroyed by the accompanying nitrogen, which plays no part in the generation of heat. This is due to heat being abstracted to expand the nitrogen uniformly with the products of combustion, which results in a lower mean temperature. Thus, with carbon $72 \times 8080 / (44 \times \cdot 2164) + (32 \times 3{\cdot}29 \times \cdot 2438) = 2755^\circ$ C., showing a degradation of thermal effect to the extent of 27 per cent.

We shall now investigate hydrogen in the same manner. 1 part by weight of hydrogen combines with 8 parts of oxygen, producing 9 parts of steam. The specific heat of steam being ·4805 heat units, the calorific *intensity* would be $34462 / 9 \times \cdot 4805 = 7969$ C., a number which represents the maximum amount of heat capable of being imparted by the total reaction of the primitive gases.

It has been shown that only a portion of combustible gases enter into combination, a fraction remaining in the region of highest temperature in presence of a corresponding proportion of oxygen, the heat in this part being sufficiently high to effect dissociation; but for ordinary purposes there is no advantage in discussing this matter in so exhaustive a manner, because the fundamental results will give relative figures for comparison, and will prove quite as serviceable as if we did.

The high degree of temperature shown in the last equation is, however, modified by the latent heat of the steam produced. Thus, if we assume that the combination be instantaneous and complete, and that the latent heat of the steam be 537 heat units, then the calorific intensity would be $34{,}462 - (9 \times 537) / 9 \times \cdot 4805 = 6857^\circ$ C.

Again, if the combustion takes place in air, a further degradation of thermal effect takes place. $34{,}462 - (9 \times 537) / (9 \times \cdot 4805) + (8 \times 3{\cdot}29 \times \cdot 2438) = 2{,}761^\circ$ C.

We are now in possession of all the data necessary, and the above equations render the calculation of the calorific effect of any gas or gaseous mixture a question of extreme simplicity. Applying these principles to that of marsh-gas burning in oxygen, we find that 8 parts by weight unite with 32 parts of oxygen, producing 22 parts of carbonic anhydride and 18 parts of steam. The density of marsh-gas to hydrogen is as 8 : 1, and as the total calorific power is 13,063, we have for temperatures above 100° C. in oxygen, $13{,}063 \times 8 / (\cdot 4805 \times 18) + (22 \times \cdot 2160) = 7{,}794^\circ$ C., and for temperatures below 100° C., $(13{,}063 \times 8) - (18 \times 537) / (\cdot 4805 \times 18) + (22 \times 2160)$. For temperature in air above 100° C., $(13063 \times 8) / (\cdot 4805 \times 18) + (22 \times \cdot 2160) + (32 \times 3{\cdot}29 + \cdot 2438) = 2{,}690^\circ$ C., and for temperatures in air below 100° C., $(13{,}063 \times 8) - (18 \times 537) / (\cdot 4805 \times 18) + (22 \times \cdot 2160) + (32 \times 3{\cdot}29 \times \cdot 2438) = 2{,}429^\circ$ C.

Again, with olefiant gas we have its total calorific power as being 11,858 heat units, and its density 14 : 1, which on combustion will unite with 48 parts by weight of oxygen, and produce 44 parts of carbonic anhydride plus 18 parts of steam. Therefore its calorific intensity burning in oxygen at temperature above 100° C., will be $(11858 \times 14) / (\cdot 4805 \times 18) + (44 \times \cdot 2160) = 9{,}152^\circ$ C., and for temperatures below 100° C., $(118{,}58 \times 14) - (18 \times 537) / (\cdot 4805 \times 18) + (44 \times \cdot 2136) = 8{,}619^\circ$ C., In air, for temperatures above 100° C., $(14 \times 11{,}858) / (\cdot 4{,}805 \times 18) + (44 \times \cdot 2160) + (48 \times 3{\cdot}29 \times \cdot 2438) = 3{,}106^\circ$ C., and for temperatures below 100°C., $(14 \times 11858) - (18 \times 537) / (\cdot 4850 \times 18) + (44 \times \cdot 2160) + (48 \times 3{\cdot}29 \times \cdot 2438) = 2{,}896^\circ$ C.

To make the citations complete, we shall now examine carbonic oxide, burning in oxygen and air. Of course, we have no latent heat of steam in this case. The calorific power of carbonic oxide is 2,403 C.; and its density is 14 = 1. On burning, 14 parts by weight combine with 8 of oxygen, producing 22 of carbonic anhydride. $2403 \times 14 / 2160 \times 22 = 7{,}069^\circ$ C., and burning in air, $2403 \times 14 / (\cdot 2163 \times 22) + (3{\cdot}29 \times 8 \times \cdot 2438) = 2{,}996^\circ$C.

Whatever difference of temperature may exist between the values given above and that actually obtained by experiment, is due to the excess of atmosphere which necessarily surrounds the flame, the specific heat of which becomes a divisory function in the calculations.

Robert Tervet.

Clippens Oil Works, March 16th.

COAL-TAR PRODUCTS.

(*Continued from page* 616, *Vol. XXXIV.*)

[19843.]—The figures in the first columns, under B.P.'s, are not the actual boiling points, but the temperature at which distillation commences. All the figures given refer to products from English coal tar; in the case of Scotch naphthas, the specific gravities are usually lower. Benzols made from Scotch naphthas are not so valuable for colour-making owing to the presence of non-nitrifiable bodies; hence the buyers of benzol usually insert in their contracts the condition "that it (the benzol) shall be a product of pure English coal-tar." The following is the usual method adopted for testing commercial benzols: "100 cubic centimetres of the sample, which shall fairly represent the bulk, are placed in an ordinary 6oz. retort connected with a Liebig's condenser. The thermometer should be so fixed by means of a perforated cork, that its point shall be ⅜in. from the bottom of the retort. Heat is applied to the retort by means of a Bunsen burner; when distillation has commenced, the heat is so regulated that the distillate shall come over in separate drops. When the required temperature is reached, the heat is withdrawn, and after a few minutes the number of cc. distillate is read off; the contents of the retort, after cooling, are added to distillate in burette, and the loss, if any, is added to the percentage as registered by distillate. Since it is often impossible to obtain fair ebullition in a new clean glass retort, in important tests of benzols, retorts which have been in use some time, and have a slight coating of carbon on the interior, should be used.

As the thermometer invariably rises from half to one degree after the heat has been withdrawn. The heat should therefore be withdrawn a little before the required temperature is reached.

This test may also be influenced to the extent of two or three per cent. by a rise or fall in the atmospheric pressure. According to a recent writer in the *Chemical News*, a sample of 30 per cent. benzol made from Scotch tars was influenced to the extent of 12° per cent., by a rise or fall of about one inch in the barometric column. The same writer afterwards admitted that a sample of 30 per cent. benzol made from English tars was influenced, under the same conditions, only to the extent of 4 per cent. It may be well, since the influence of varying atmospheric pressure on the testing of benzols, light oils, &c., has given rise to some discussion, to briefly comment on this phase of the subject.

Mr. A. H. Allen has stated that a difference of 1in. in the height of the barometric column makes a difference of one degree Centigrade in the boiling-point of benzol. Hence, if this be so, if we wish to obtain an approximate idea of the influence of atmospheric pressure upon the results of tests of coal-tar, naphthas, &c., it will be necessary to note the different percentages at the temperature specified by the test, and at a temperature one degree higher or lower. Let us first take one of the crude products—viz., light oil: the sp. gr. of this light oil varies from ·940 to 1·000. It will be seen from the percentage of distillates at every rise of 5° C., as given below:—

Sp. Gr., ·943; B.P., 100°.

C. 110	C. 115	C. 120	C. 125	C. 130	C. 135	C. 140	C. 145	C. 150	C. 155
5	8	10	16	20	23	26	30	34	37

C. 160	C. 165	C. 170	C. 175	C. 180	C.
41	44	47	50	54	percentage.

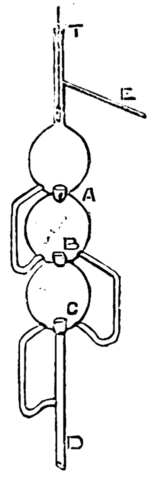
that a difference of one degree Centigrade can practically have but slight influence upon the testing of light oils. I have given the percentage of distillate at temps. from 100° C. to 180° C., because in the buying and selling of light oils there is no specified temperature at which the light oils shall yield a certain percentage of distillate, varying temps. being fixed by the various buyers and sellers. In the case of "once-run naphtha," a more valuable product, this is generally specified to yield a certain percentage at 120° C. A sample giving 41 per cent. at 120 C. gave 43 per cent. at 121 C., a sample giving 50 per cent. at 120 C. gave 53 per cent. at 121 C.; therefore, it is probable, though not certain, that a rise or fall of 1in. in the barometric column would affect the result of test two or three per cent. in these cases. I say it is probable, for it does not follow that because the boiling-point of pure benzol is influenced to the extent of one degree under certain conditions of atmospheric pressure, that the boiling-point of a mixture of several hydrocarbons will be affected under similar conditions to the same extent. When we come to the higher class of benzols we find that one degree temp. makes a greater difference, thus:—Benzol yielding 30 per cent. at 100C. yielded 40 at 101 C.; yielding 47 per cent. at 100 C. yielded 52 at 101 C.; yielding 51 per cent. at 100 C. yielded 58 at 101 C.

In the case of benzol yielding 90 per cent. at 100° C., 1° rise or fall of temperature can make but little difference, there being but 10 cubic centimetres of higher homologues of benzol left boiling in retort, the temperature rises very rapidly. Mr. B. Nickels has published the following method of estimating the percentage of carbon bisulphide present in 90 per cent. benzols:—100 cubic centimetres of the sample are agitated with one gram. of potassium hydrate dissolved in the smallest quantity of boiling absolute alcohol, occasionally during a period of 30 minutes; the mixture is then filtered, the filtrate washed in a glass stoppered separating funnel with its own volume of slightly warm water, the wash water run off, and washing with cold water repeated two or three times. The benzol is then run into a dry bottle, and agitated with a little plaster of Paris to dehydrate. Two samples of English 90 per cent. benzol were treated in the above manner and tested, before and after treatment, in Townson and Mercer's fractionnater.

	No. 1. Before Treatment.	No. 1. After Treatment.	No. 2. Before Treatment.	No. 2. After Treatment.	
Distillation commenced	81·4	83	81	83	C.
10 per cent off	83	84·1	82·5	83·8	C.
20 ,, ,,	84	84·9	83·2	84·4	C.
30 ,, ,,	85	85·4	84·0	85·1	C.
40 ,, ,,	85·5	86·2	85	85·5	C.
50 ,, ,,	86·5	87·1	86	86·2	C.
60 ,, ,,	87·7	88·2	87·1	87·5	C.
70 ,, ,,	89·5	90	89·2	89·3	C.
80 ,, ,,	93	94	92·5	92·5	C.
90 ,, ,,	100	102	100	100	C.
95 ,, ,,	113	119	117	116	C.
Specific gravity	·8819	·8798	·8832	·8812	

It was found that the addition of half per cent. by volume of carbon bisulphide to the treated benzols restored to them their original gravity. It was, therefore, concluded that the above samples contained half per cent. by volume, or 0·7 per cent. by weight, of carbon bisulphide.

Townson and Mercer's Fractionnater.—At A, B, and C are inserted small conical cups of fine copper gauze. D is inserted through a cork, fitting into the neck of an 8oz. flask. When distillation is going on, the distillate condenses on A, B, and C, and thus washes the ascending vapours, whilst the surplus liquids, condensed, pass, by means of the side tubes, back into the flask; the lighter vapours passing forward through E to the condensing apparatus. A thermometer is inserted at T.



200 cubic centimetres of 90 per cent. benzol, after extraction of carbon bisulphide, were distilled in the above apparatus. The first 100cc. distillate from this, which distilled off between 81° C. and 84·5° C., tested in the ordinary manner in 8oz. retort, with thermometer immersed in liquid:—

B.P.	81C.	82	83	84	85C.
80C.	5%	15%	38%	69%	82%

With thermometer in vapour;—

79	9	45	65	76	82%

Mr. B. Nickels gives the following as a proximate analysis of good 90 per cent. English bemzol.

Carbon bisulphide	1·5 per cent.
Light hydro-carbons, sp. gr. 872, not nitrifiable, probably chiefly amylene and acetonitrile......	3·5
Benzene, sp. gr. ·885 and distilling wholly within a range of 2°.	78·4
Toluene, sp. gr. ·8715, and distilling within 2°	16·6
	100·0

The following figures may serve to illustrate the efficacy of this apparatus as a fractionnater.

A sample of impure commercial toluene which tested in the ordinary manner showed:

BP.	110C.	115C.	120C.
107C.	20%	52%	74%

The first 25 per cent. distillate, obtained by distilling in ordinary retort; and retested, gave results as under A. The first 25 per cent. distillate, obtained by distilling in fractionnater, and retested, gave results as under B.

	BP.	100C.	110C.	115C.
A =	100	—	64	84
B =	96	42	90	—

Chemistiana.

(*To be continued.*)

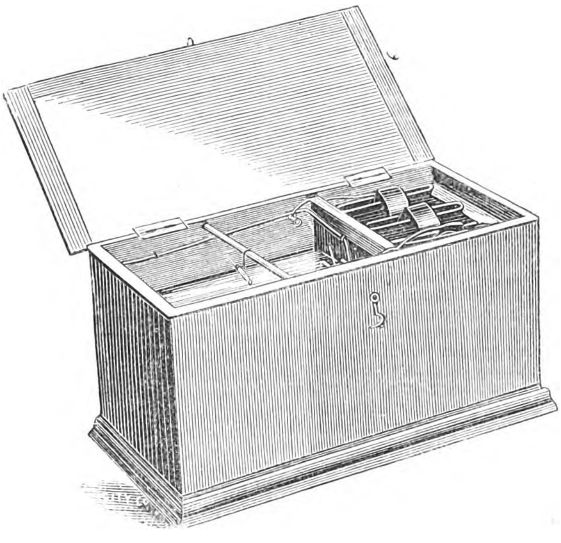
PATENT ELECTRO-PLATING APPARATUS.

[19844.]—I take the liberty of sending you a sketch of my new apparatus for plating either silver or nickel. Knowing how much nickel and silver plating are inquired after in your valuable paper, I thought the matter would be of general interest. The apparatus has been devised for the many and varied workers in metal who desire to put a superior finish on their work.

There are many small articles which appear too trifling to send to a professional plater, and to those working or dealing in such, this apparatus is of great value. It is of good service in technical colleges for class demonstration, and is particularly adapted for amateurs in the fascinating occupation of electro-plating.

The construction of the apparatus forms one of its several merits, bath and battery being in the same mahogany case. The electromotive force is under 4 volts, and the plates having great surface, a considerable quantity of current is obtained. In many cases, nickel-plating is done with too much electromotive force, the result being that the nickel is very easily chipped off. No acids are used in the battery, and the zincs do not require amalgamation, and the battery is *very constant*. The apparatus is on view at the Crystal Palace exhibition on the stands of Messrs. Dale and Co., also Messrs. J. Orme and Co.; they may also be seen at Messrs. Mayfield and Co.'s, 41, Queen Victoria-street; Messrs. Dale and Co., Little Britain; Messrs. Orme and Co., Barbican, and Mr. Paterson, Little Britain, where every information may be obtained. **John E. Chaster.**

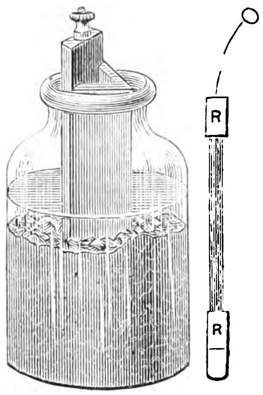
35, Ward's Buildings, Deansgate, Manchester.



TOLMAN'S SAL-AMMONIAC CELL.

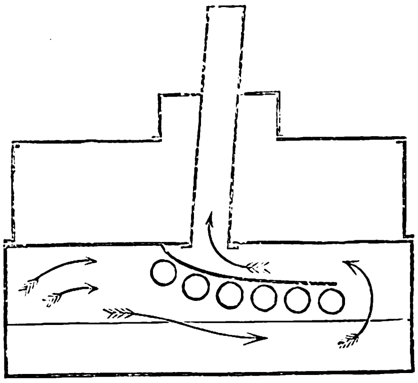
[19845.]—We well know the trouble of making up manganese cells, and when made, total failure in a few weeks. It is not generally known that a plate of carbon and zinc immersed in a solution of sal-ammoniac gives off a fair current, and rings an electric bell fairly well; it would surprise a great many who have not tried it. The fact of this led me to devise the present form of cell, which I have tested for 12 months; on one occasion it was in circuit for two days, with an electric bell and indicator of very little resistance. Of course it was soon exhausted; on disconnecting for less than five minutes, it recovered itself quite equal to its accompanying cell, a new-pattern Leclanché. It has never failed since; have repeatedly tested it; it works a large electric bell: resistance of coils 1·5 ohm.

The arrangement consists of three carbon plates placed to form a hollow prism, and fixing an india-rubber band on each end; one of the carbon plates, which has the terminal on, is 3in. longer than the other two, and is soaked in paraffin-wax for 4in.; the other two are dipped an inch in the wax. The one carbon being longer, the salts cannot creep to the connection. If ready, place the prism in the centre of a glass bottle, and half-fill with broken gas carbon, about the size of beans: on no account use any carbon dust; gently shake, to settle in the smallest compass; fill up within an inch and a half of the top with clean water. Then pour some (not very hot) melted paraffin on the top of the water by degrees, allowing it to set firm before any more is added, till it is level with the top of the jar or bottle; this forms a wax cork: and keeps the carbon prism in place, and prevents salts creeping. Now pour water out. Three parts charge with a saturated solution; also place in a tablespoonful of powdered sal-ammoniac. The zinc rod should be a little longer than the cell, with a piece of rubber tubing, R, on each end to prevent contact with carbon. Take care of any carbon getting loose in the prism, and do not use any greasy vessel. **George Tolman.**



MODEL STEAMBOAT AND BOILERS.

[19846.]—I have noticed a good many queries for dimensions of boilers and best form for driving model engines, and have expected to see some arrangement of tubes suggested in addition to the plain, flat piece of heating-surface which is given



by the ordinary form of boiler. Perhaps it will be said that anything beyond this entails more work and complication; but I think it is quite worth while to go to a little trouble to obtain a boiler which would give a larger and more effective heating-surface, the space available in model steamboats being generally limited.

How would it do to put a series of water-tubes running across the firebox from side to side, commencing at about the middle of its length, and ending within an inch of the end and about 1in. from the top, the chimney to be near the middle, so that the flames from lamp, after heating the first part of firebox, would have to pass under the water-tubes and turn up at the back, and then heat the other half of firebox and pass up the chimney? The sketch will show the arrangement clearly.

It would be very interesting if any reader who has a good model boiler which has any special arrangement of heating-surface, if he would send description, and what size engine it will drive.

E. L. P.

LENSES AND THEIR FOCI.—TO "ORDERIC VITAL" AND OTHERS.

[19847.]—THE next points on which information is wanted relates to lenses singly, and I will put it as briefly as possible. A plano-convex lens, receiving parallel rays on its convex surface, reflects them to a focus at the diameter of curvature; but if the rays falling on it are convergent or divergent at any given angle, how can the new focal points be determined?

If a periscopic lens have its concave surface of a radius equal to the distance from it of a radiant point, and its convex surface $1/n$ that of the concave, where will the focal point be situated?

As variations of the first query, how is the result affected when equi-convex or crossed lenses are used, and of the second query, when the convex surface has a radius greater than the concave?

If two lenses of different foci, but of the same diameter, and so arranged that their foci were on the screen of a photometer, were simultaneously used to transmit parallel rays, would the intensity of the light-spots on the screen be equal or inversely as the squares of the focal lengths? Solar rays are supposed to be used.

Lens.

REFLECTING TELESCOPE.

[19848.]—So much has been written on the adjustment of mirrors, and I must plead guilty to it myself, that those who have not instruments may perhaps suppose that it is beset with difficulties, and may be discouraged from procuring reflecting telescopes. But exactly the reverse is the case. When first I had one, thanks to Mr. Calver's instructions, I never had any difficulty in getting a good adjustment, but I saw very soon the perfection of which it was capable, and I resolved not to rest until the whole thing was accomplished with perfect accuracy and simplicity.

It clears the way, in the first place, to know what is necessary and what is not; and this, perhaps is best stated by saying that the observer has to do with nothing but the mirror, the flat, and the eye-tube—and the beginner should not meddle with the eye-tube until he is quite at home with the other adjustments. The eye-tube is set by the maker, and will most probably, from a good maker, not require altering. So that it is reduced to the two mirrors.

Perfect accuracy, with simplicity, is attained in the adjustment of the large mirror, as has already been described in the ENGLISH MECHANIC, by bringing the spot on the mirror central in the reflection of the flat. Nothing can be easier and simpler, and it is the cardinal adjustment, for unless this is right, nothing is right or can be made right, except by a balance of errors, by adjusting on a star, which I would warn all beginners against as vexation of spirit.

The simplest adjustment of the flat is, with the eye-tube drawn out to power of 200, to make it concentric with the mirror. This is all—and quite sufficient for the first six months, or until the observer wishes to try the inner pinhole. A simple form of this is to fit a piece of cardboard to the tube and make a hole quite central ¼in. diameter. The adjustment of the flat is made at 200, because if the eye-tube should be slightly out of truth, it will be right at the 200, and the change to other focusses will then be so small, that the error, if any, will be hardly appreciable.

Fordingbridge. **T. Westlake.**

P.S.—It may, perhaps, be thought rather unprofessional to make a spot on the mirror—but I do not hesitate to say, that no eye is correct enough to insure a perfect adjustment by only bringing the reflection of the flat central in the mirror, and the best observers will, if they try the spot, be the first to acknowledge that they have with it a simplicity and accuracy which is otherwise quite unattainable.—T. W.

ADJUSTMENT OF REFLECTORS.

[19849.]—A CORRESPONDENT, writing to me after the appearance of Mr. Haren's letter, remarks:—"Notwithstanding so much is said about the atmosphere of America, there seem to be fogs there, and Mr. Haren seems to be in one." Mr. Skelton and Mr. Westlake have been at the pains to describe methods they use, and by which they readily and easily adjust their telescopes accurately, and obtain perfect results. Yet Mr. H., after all, imagines their instruments "may be glaringly out of gear." Mr. H. is not the only one, perhaps, who rides his "hobby" to death, and makes troubles where none exist. It certainly is one of the easiest things to see when a mirror is leaning from axis of tube by its reflecting more of that part of tube towards which it is leaning. And Mr. Skelton has shown that the amateur needs no better plan to bring the mirror quite true than his spot in its centre. The simple plan of measuring with a rule will show whether the plane is in the axis of tube; guessing is not needed.

G. Calver.

VIOLIN SOUNDBOARD WOOD.

[19850.]—SWISS pine, commonly so called, is really a harsh, stiff wood, its principal requirement being a straight grain, some closer together than others. Now, this wood comes from America, that treasure house for timber of all kinds. Australia does not compare, and although the "Kauri" pine of New Zealand is a beautiful wood, yet is too wiry or split-like for a good resonance. For the violin proper we must have strength to resist the down-pressure of the strings, and where this cause is eliminated, as per Berliner's patent, yet a reaction is so necessary that a strong wood is still required. The piano here has no comparison, because the actional vibration is direct—that is, as the hammer moves the string, so the string moves the soundboard, but in the violin the bow pulls the string from side to side, causing a vibration that has to make its way (and does) through the bridge (which it ought to rock, but can't through the pressure), through the soundboard, which is at right angles to the bridge and string, and then through the soundpost to the back. The said soundpost is again at right angles to the soundboard and back, but the return action of the vibration, starting from the back, is turned in the right direction to move the soundboard bridge and string. Yes, though the bow still moves the string the contrary way, yet the reaction moves soundboard up and down, or the right way. Now, if this reaction was not required, much softer wood could be utilised, and indeed would be an absolute necessity; but what with the pressure, &c., a harsh, stiff wood is thus the thing; as we use enormously stiff strings for pianos, so I suppose that a stiff wood soundboard is right, the parties are agreed; but for violins where soft gut is used, soft wood should be the rule. The only way to have this is to place the string in relation to the soundboard as it is placed on a piano, and (shall I blush to say it?) on the new violin. I know many of "ours" will be improving on the idea, but I warn them off the Swiss pine; it's only a waste of time and money. I hereby return thanks to "ours" for their confidence and inquiries, but as I had an ugly rush of clients, I thought this one reply would do for all, and somewhat relieve a **Fiddler.**

MEDICAL REPLIES.

[19851.]—OPACITY OF CORNEA (46411).—This subject is fully dealt with in the article (page 542, No. 881) to which "J. W." refers. When once pustular ophthalmia has produced ulcers and left scars upon the front of the eye, the pupillary opening is obscured permanently, and the sufferer must select some employment which does not require keen or discriminating vision. Simple bathing with warm water or with cold, strong, perfectly-clear tea, is the best thing that can be done to such eyes when they become irritable and inflamed. "J. W." may have other complications, such as vascular cornea, or inflammation of the roots of eyelashes; but here, again, he can only be prescribed for by some one who can make an accurate diagnosis, and his own description is not clear.

"J. R.," who asks me to prescribe for convulsive attacks in his child, must consult a local medical practitioner, who can examine the child.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

HINTS TO EMIGRANTS.

[19852.]—DURING the last few months a large number of subscribers to the ENGLISH MECHANIC have written to me for advice as to emigrating to this country. I have answered their questions to the best of my ability, and now I have a letter before me from a young man living in co. Meath, Ireland. Some of his queries and my answers may be of interest, and I hope of value to others, who, like him, desire to gain information of a reliable nature concerning this country, and the inducements it offers to the intending immigrant. In a letter which this young man (whom I will call Charles B——) addressed me in October last, he stated that he had worked on a farm all his life, but was fairly well educated. He asked if it would be well for him to come out here as a clerk. I dissuaded him from this, assuring him that the clerk market was already overstocked, while there is always plenty of room for farmers.

In his letter of Feb. 23rd, he refers to the fact that all the vigorous men appear to be leaving Ireland for this country. He states "one man who left from about here last year has written home to say that he is earning 60 dols. per month in New York." I quote this remark for the purpose of pointing out that 60 dols. per month in New York is not worth more than 30 dols. in London, while a man could live very comfortably in the country in England for even less. If a man goes to New York city from an Irish farm and seeks work, the chances are that he could get only the meanest kind of labour at wages which would secure him only the most miserable accommodation. I have seen too much misery in New York city to advise anyone ever to go there to live. It is an excellent place to leave.

My correspondent says that he has been used to overlooking men, although at times he would turn his hand to hard work. He asks if, under those circumstances, it would not be better to "reside somewhere on a farm in America, and gain experience as to the ways of the people before investing any money." Most certainly, Yes. That is the only sensible way. Let me say that unless Charles B—— knows some friends who are farming, to whom he can go, a good way for him to do is to strike out himself into the Far West, take his fortune in his hands, and take the first work that turns up. This is by no means a dreadful or risky thing to do for a man of pluck. If he is going to farm it is of no use to stop in a city, and but little use to advertise promiscuously, although if he comes across a newspaper circulating in the neighbourhood where he would like to settle, he might do something in this line. But there are a variety of ways of getting the kind of work he wants. He might see an advertisement, or meet someone in the train who could help him.

Let me say a word here as to the kind of life my friend will find in the Western States. Very little of the land in some of these states is settled. He may find himself out of society, surrounded by people speaking all kinds of tongues, without schools or churches—that is in, say, Kansas, Iowa, Utah, Dakota, &c. If, however, my correspondent would not mind sacrificing a possible future chance of owning a large Western farm, if by so doing he could secure more comfort for the present, he should have little difficulty in securing work on a farm further east—say, in New England or a Middle State.

My correspondent asks me, "What amount of capital would give a man a fair start in Kansas or Missouri?" This is a question difficult to answer. Charles B—— had better do as he suggests, and go and live on a farm first as a hand; then he will be better able to judge for himself as to the capital required.

He also asks, "What are the extremes of heat and cold in these States, and are all immigrants likely to be attacked with the ague or any other disease?" The extremes of temperature are rather great in some parts of these States; but the atmosphere is dry, and 90 degrees is borne without much inconvenience. The thermometer rarely goes down to zero in Kansas in the winter. In Minnesota it goes down to 40 degrees below zero sometimes. The ague is very prevalent on marshy ground; but if an emigrant chooses a healthy location, which is easily done, he will be safe.

"Are there good markets for all you would produce on your farm?" Yes, if your farm is near a railroad.

"Are mosquitoes, flies, and snakes very prevalent in Kansas and Missouri?" In some parts, especially on low ground, mosquitoes are abundant. Snakes are found in some localities, but the trouble from them is not great.

I have answered all my correspondent's questions to the best of my ability. Let me say that the Mid States I have been referring to chiefly—Kansas and Missouri—are warmer than Ireland. It might suit Charles B—— better to go to Iowa, or Minnesota, or Wisconsin, where 30° below zero is not as difficult to bear as zero in the British Isles. In all of these States he would find an abundant opportunity to make his way, and act as the pioneer for his family. Or if he desired it, he might go to Canada, where the advantages are equal to those to be had in this country.

R. M. Tuttle.

Providence R.I., U.S.A., March 10th.

TO "FELLOW-WORKMAN."

[19853.]—EXCUSE a kindly criticism; but why recommend the amateur to open brass holes to fit pivots when fitting a new verge? If he can run the pivots to fit the jewel-holes, surely he can get them fine enough to fit brass holes, which will be much less trouble and not nearly so detrimental to the watch. I am aware some self-taught men do act upon this plan, and also open the hole in the balance so as to save the turning; but of course, in nine cases out of ten, this way of procedure will put the balance out of poise, and make the watch so that it can never be relied on as a time-keeper.

Perhaps "Fellow-Workman" will excuse me if I say here that he might have given a few more lessons on the cleaning and larger repairs before he gave instructions how to put in a new verge, for we cannot get the amateur to the apex of the horological hill all in one lesson. Tempus.

HOW TO MAKE A CHEAP AND ORNAMENTAL BOOKCASE.

[19854.]—THE reply to letter 19777 is not satisfactory; others than the querist require the same information. He who answers well will confer a public good. I admire Mr. King's ideas; but as I view his drawing I am seized with the idea of huge folios coming down with a crashing weight on my skull! Moreover, there is a difference between *jam* and *books*. The former, in large pots, occupies the top shelves, of course; but the man who makes use of books deals more frequently among his larger ones. For my own part, no book on my shelves remains untouched long. The red ink-stain is perfectly horrible. Why not use blood? Wood-stains can be had at 6d. per bottle, and what can be better? As I am also waiting for instructions to make a cheap and ornamental bookcase, will your readers help? Beta.

LATHES AND LATHE-MAKING—TO "C. H. D."

[19855.]—I HAVE not seen an account of Booth Bros. "Overhead," but have sent to the firm for description. The exact details of planer sent by you I have never quite made out. The drawing suggests a compact and good machine, which I believe it is. O. J. L.

A NEW BICYCLE BACK-WHEEL BEARING.

[19856.]—I SEND the accompanying sketches (drawn half-size) of a back-wheel bearing of my own design, which I have made and found to answer perfectly, thinking they may be useful to some of my fellow-readers. They may be found suitable for either bicycle or tricycle back wheels. I claim for them the following advantages:—They are dust-proof; the wheel cannot drop out; they are very strong, the pin being one size all through. All the wearing parts are of hardened steel, and are renewable. They can be adjusted in a moment.

No more tools are carried, as the key can be combined with the "tommy" for turning centre of head. They *are not patented.*

TO TIGHTEN THE BEARINGS.—Loosen the lock-nuts, turn the pin with the key till the wheel will turn freely but without side shake, then lock one nut, holding the pin in the key to prevent its turning, then lock the other. In practice it is best to allow a little shake when turning the pin, as the nuts tighten the wheel a little in locking.

TO TAKE THE WHEEL OUT (WITH BALLS).—Take out the three screws from each dust-cap, take off the lock-nuts, spread the forks by turning the pin the reverse way until wide enough and remove the balls (they will shake out)—first one side and then the other. Put a piece of wood between the forks, to keep them wide apart; then take out the screw that prevents the outside cone turning the side the key is not. Turn the pin as in tightening the bearing, but allowing the loose cone to turn with it. When tight, turn the reverse way, now keeping the loose cone from turning (a piece of wire may be thrust through the fork-end into small screwhole) until loose cone comes off pin. Remove it, and, with a small screwdriver, turn forwards until the pin is out of cone. Why the screwdriver is used is because the key would not turn inside cone (the tommy-end might be filed flat for this duty). Remove pin, then take out screw preventing key-end cone turning, and the wheel will come out.

TO PUT THE WHEEL IN (WITH BALLS.)—Place the wheel between forks; place one outside cone in position, with dust-cap over it, remembering the left-hand threaded cone goes the right-hand side of machine. Put pin through fork and hob the side the cone is not, turn pin until it is screwed far enough into cone to admit of the other outside cone being placed in position; place it so, with the dust-cap over it; turn the pin the reverse way from before, but allowing the cone first put in to turn with it, the last one, of course, remaining still. When the cones are tight in the hob, should the pin be too short one side and too long the other, turn the pin the way to loosen the wheel, allowing the cone the side the pin is too short to turn with the pin. When open enough, turn the reverse way, but now keeping the cone the short side still, and allowing the long-side cone to turn with the pin. When pin is properly in place, put in the screws that prevent cones turning, spread the forks by turning the pin, put the balls in one side, turn the wheel over, and put them in the other; close cones on then till tight by turning the pin, put in dust-cap screws, and put on lock-nuts.

These directions look very formidable on paper; but, in practice, they are very simple. The coned bearing is tightened, removed, and replaced in the same manner, but without balls, of course. If any reader wishes to make one I will give the method I used without a slide-rest being required.

Fig. 1 shows a combined key and "tommy" for turning centre in head.

Fig. 2 shows coned bearing; N, lock-nuts; F, fork ends; C, cones; P, pin; L, left-hand thread; R, right-hand ditto; K, key square for adjusting; E, eye to take screwdriver.

Fig. 3 ball-bearings; N, lock-nuts; F, fork end: S, screw to prevent cone turning; C, cones; D, dust-caps; B, balls; I, inner cones; H, hub; O, oil-hole; P, pin; L, left-hand thread; E, eye to take screwdriver; R, right-hand thread; K, key-square; S. P., small pin to prevent inner cone turning. Ixion.

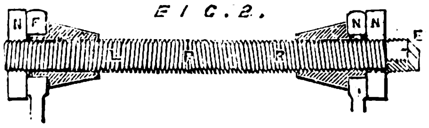

FIG. 3

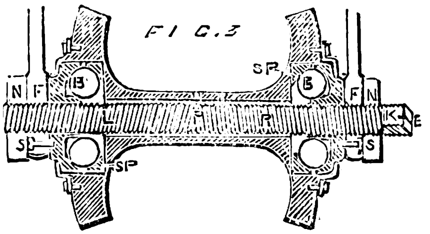


A SCREWDRIVER IMPROVEMENT.

[19857.]—MOST people who use screwdrivers must be occasionally inclined to use strong language at their persistency in slipping out of the nick, and their refusal to go into it. I do not know how it has happened never to occur to me until the other day—nor to anybody else, so far as I know—how to prevent this, by a very simple addition, especially now that round screwdrivers have almost superseded flat ones, being so much nicer to handle.

All that is wanted is a short tube, big enough to inclose the screw-head somewhat tightly, but only spring-tight, so that it may rise as the screw-head comes near the wood. Also, we have to provide for heads of different sizes with the same driver. All this can be done by just turning up a strongish tin tube, 3in. or 4in. long, like a slate-pencil case, big enough to slide over the widened point of a round screwdriver, and then fitting spring-tight on the shank by means of a piece of leather wrapped round it; and for larger screws than usual, you might pull that socket off and put a larger on, with a thicker piece of leather. I find it answers perfectly. You need not even look at your screw, but just put the tubed screwdriver on, and turn. It will drop into the nick at the first half-turn, and stay there till the screw is screwed home. In unscrewing, of course, the tube must be slid back until the screw-head is clear of the wood, and then slid down during the rest of the unscrewing.

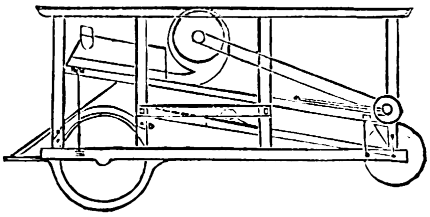
March 20. Edm. Beckett.

Preserving Meat.—A method of preserving meat by causing the heart of the animal to pump boracic acid into the tissues has been recently patented. A sheep, for instance, is stunned by a blow, and blood being withdrawn from the left jugular vein, a strong solution of boracic acid, kept at blood heat is injected. In a few minutes, the heart of the still living animal has pumped the antiseptic fluid into all parts of the body, and the sheep is then killed in the ordinary way by the butcher. The cost is said to be less than 6d. per sheep, and the meat will keep for five or six weeks in summer.

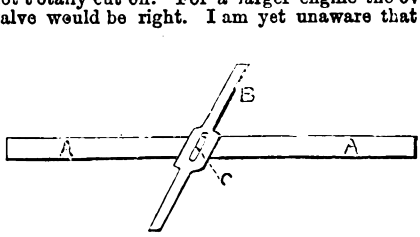
REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45516.]—**Hand-Thresher.**—I have sent rough sketch of what I think "Strathtay" would require. The best thing I think he can do is to make the whole frame, as shown, and take drum and gearing, &c., out of old frame, and put it in the new, and then he would get the whole in one piece. It would not take him so long to shift it as it would to fit everything on to the old one. You omitted to mention the height of drum-centre from floor, but I have supposed it to be 3ft. 6in. The length of whole frame over posts would then be 8ft. 2in, 3in. sq. wood. The distance between the two posts at drum end is about 1ft. 9in. inside the posts, and then the other one just between the two. There are two shakers 6ft. long, the sides of them being 5in. broad, about $2\frac{1}{2}$ft. from back end, and then tapered to 3in. at point. They are $\frac{7}{8}$in. thick. The crank-shaft is placed about 2ft. from back end, and the points rest on rollers. The crank-shaft should be 1in. diam. and $2\frac{1}{2}$in. of a throw, that is from centre to centre. The journals are 3in. long by $\frac{5}{8}$in. diam., and the bushes made of beech, as brasses rattle terribly. The shakers are driven off small crank-shaft at the point, at the same speed as riddle. Next the riddle is 8ft. 4in. long, and is hung on four springs, and driven by a rod off small crank-shaft. The sides are $3\frac{1}{2}$in. broad, by $\frac{7}{8}$in. thick, and the bottom of it is all close until about 30in. from low end, and then the first riddle is put on. It will be seen from sketch that the riddle frame is deeper here; but you can determine that after you get shakers in, as you will require to keep the riddle as close to shakers as it will work freely. The second riddle is put beneath the first, and the blast blows in between the two. The size of holes in first riddle to be $\frac{7}{8}$ and in second $\frac{3}{8}$. It will be seen that from the rocking motion of the riddle the grain is gathered down to the spout in the corner and shaken out to the floor, the chaff passing out at the end. The fan will be 15in. diam., and the flights, three in number, about 3in. broad. The spindle would do $\frac{5}{8}$in. diam., journals $\frac{1}{2}$in. diam. by 1in. long. The shakers, riddle, and fan could be driven separately at the point about 18 to 5, and I think that a man should drive it easily. The blast would require to be driven about double the speed of riddle; but as I have no more time at present, if "Strathtay" thinks this would suit him, I would gladly give him any more minute information, either through the "E.M." (if the Editor does not object) or by letter.—WAS-HEIL.



[45687.—**Throttle Valve.**—"J. J. A." certainly can't have read the original query carefully. The throttle-valve over which so much valuable space is being wasted really was for a very small model engine, and for such it is not necessary to go to the extent of using an oval valve. Therefore, for a small model, the circular disc is quite sufficient, as from the small capacity of the steam-chest a little leakage is a benefit, as the steam is not totally cut off. For a larger engine the oval valve would be right. I am yet unaware that I used any terms that were incorrect, or that were not known to practical workers. It rests entirely with the Editor, in his discretion, as to whether it is worth while to engrave the sketch I have inclosed of the pattern of the valve showing the chucking spindles. A and A are the spindles, B the valve shown edgeways. C the flat passage through which the spindle goes that it turns on. I have yet to learn that it is needed to show a dia-



gram of a drill to bore a square hole, as, in the first instance, I did not use the words he assumes to have quoted, and further still, no amateur possessing even a superficial knowledge of engine construction would want to be told that the drilled (not cast) hole was for a steady-pin passing through the casting and the valve spindle, and that it did not refer to the spindle aperture itself.—Sunlight.

[45885.]—**Yellow Wash for Funnel.**—Yellow ochre mixed with water to the same consistency as for whitewash, and painted on with ordinary paintbrush. Do not use oil paint or varnish, unless you want it to turn brown with the heat. It will want renewing occasionally. — Marine Engineer.

[45894.]—**Acne.**—I have found it to be greatly relieved, almost cured practically, by abstaining as much as possible from butter. This may require some self-denial at first; but after a time a critical taste in bread will be developed, and butter will come to be regarded as spoiling the flavour.—Nonius.

[45918.]—**Grafting Fruit-Tress.**—I meant to have replied to this query before, but circumstances prevented me. There is one rule in grafting which is a *sine quâ non*, and that is, the bark of scion and stock must be brought into intimate connection; beyond that there is very little, as the exact shape of the cuts may be anything. Always choose for scions perfectly ripened shoots of the previous year; and as to season, the golden rule is that the stock must be further advanced in vegetation than the scion, because unless that is the case the latter will dry up for want of sufficient sap. Therefore, cut your scions as soon as the buds begin to swell, and bury them in the ground or in moist sand. As soon as the stock begins to push vigorously, insert, cover carefully with "wax," and leave the rest to nature. Take care always that the inner bark of both scion and stock are in contact. Plums can be grafted in the ordinary way, but, as a rule, they are budded in July, just the same as roses, because that operation is more certain than the ordinary grafting. Cherries should be shield-grafted — that is, budded in August; the peach the same, but gardeners have some little fancy for earlier or later grafting, according to the stock. The apple and pear can be grafted apparently at any time except winter. If "O. V." does not understand, and no skilled gardener comes forward, I will endeavour to explain further.—Nun. Dor.

[45933.]—**Soldering.**—I shall, before concluding my articles on "Plumbing," give a chapter or two upon this very important and almost unknown branch of the plumbing trade. Such a question as that put by "N. W. E." cannot be answered in Tom Hood's style of "Yes" or "No"; in fact, short answers would only mislead. Rest quiet for a short while until I can get rid of the sanitary work, and then shall come to lead-burning proper. I shall introduce it in cistern-lining.—P. J. Davies.

[45943.]—**Pressure of Water.**—If you alter the size of supply pipe to the motor you must alter the size of discharge pipe as well. You might get a little more power this way. The pressure would be slightly reduced in passing through a meter, but the stop-valve should be of the sluice-valve pattern —giving a straight thoroughfare. You ought certainly to get this, with 36lb. pres.—Labor Omnia Vincit.

[45962.]—**Glass Transparencies (U.Q.)**—As no one has replied to this query, I will endeavour to do so, as I have been giving a great deal of attention to the subject during the last three months. I use gelatine plates of the "quarter plate" size 4¼in. by 3¼in.; as magic-lantern slides are usually 3¼in. square, the plates have to be cut after they are printed; it would be a great convenience if some of the dealers would make the gelatine plates of that size. I have used several makers' plates: there does not seem to be much difference. Mawson and Swan's or Wratten and Wainwrights' are perfect, but I daresay others are as good. To proceed, then: My grocer furnished me with a biscuit-box, about 2ft. 6in. by 1ft. 6in. by 1ft. This box is set up on end, and a small hand-lamp (paraffin) placed inside; a little window, about 6in. square, is cut in the box opposite the flame of the lamp, and over this is placed one thickness of orange-coloured paper, previously varnished to make it transparent; the lamp is then lighted and the lid closed. In the same room (darkened, of course) is another lamp, with the flame turned down when not in use. The wick is about 1in., and it has a ground-glass globe. The negative to be copied is laid on a table face up, and the gelatine plate placed over it, face down; place a piece of black paper over these, and then turn up the lamp last mentioned so that the flame is about half its full height. Then place the thumbs on the black paper covering the plates, and with the tips of the fingers of both hands, raise the plates and black paper, and pressing the plates together, hold them facing the lamp at a distance of about 6ft., the time of exposure will be from 20 seconds to half a minute. Place the plates on the table as before, and turn down the lamp. The developer is made as follows: Put half a pound of sulphate of iron in a quart beer bottle and fill with water up to the top of the cylindrical portion, leaving the round shoulder and neck empty—this makes it easier to pour out of the bottle; then, in a large jug or ewer, place a pound of neutral oxalate of potash, and over this pour as much hot water as will fill three quart bottles to the same height as the sulphate of iron bottle; when dissolved, pour into the bottles. The strength of these solutions, when the salts are dissolved, will now be almost exactly that given in the printed formula. These solutions are to be mixed just before using in the proportion of three of oxalate of potash to one of sulphate of iron. About an ounce of the mixture will be sufficient, and a few drops of a saturated solution of bromide of ammonium should be added to each ounce. This keeps the light parts perfectly transparent; the mixture is poured into a square dish somewhat larger than the plate. The plate should be left in this for at least 10 minutes, but longer steeping does not do any harm. In looking at the orange light through the plate, it will be seen that the plate is almost black, and hardly a vestige of the picture is to be seen; but on steeping in the hyposulphite bath, the picture becomes beautifully clear with a clear glass for the lights, and the shades of a perfectly neutral tint. The usual washings must then be done, and the picture is complete. It will be seen that all depends on giving the right exposure; but this is soon learnt, and by using a weak light the time is more easily regulated. The appearance of the picture during the developing is no guide at all. The pyrogallic acid development is too troublesome for an amateur, and the tone is not so good. A few seconds too long in the developing-bath stains the picture yellow, whereas with the iron it may remain in for a quarter of an hour to twenty minutes, while you are printing another plate. While developing, the plate should be covered. The transparencies made in this way are admirably adapted for colouring; but this is a separate subject, and this reply is already too long. —M.I.C.E.

[45990.]—**Organ Pipes (U.Q.)**—State the scale—*i.e.*, the diameter—of your pipes, or your query will not be answered. To your last question: Yes, 2in.—J. W. W.

[46012.]—**Tile Moulds.**—The obvious answer to this query is, try whether brass strips will be better. Presumably leather is used for cheapness; but then brass, properly screwed on, might answer better. Zinc could be used instead, but probably the brass would be cheaper in the long run.— J. T. M.

[46018.]—**Turbine for Low Fall.**—If the querist will refer to "Molesworth's Pocket-book," he will find rules for calculating the power as applied through turbines, and a table of horse-power from actual practice. I quote one that meets his case: Head 2½ft., velocity of centre of buckets in ft. per sec. 9½, quantity of water 25ft. per sec., revolutions of turbine per minute 34, gave 5 horse-power. The head, it will be seen, is less than his, but the quantity is greater, so that it just about meets his case, and he may rely upon getting 4 h.-p.—S. Mayer.

[46082.]—**Driving Smith's Fan.**—"J. J. A." need not cross the Irish Channel to be convinced that a 6in. fan can easily be driven by hand at the rate of 3,000 revolutions per minute. Mr. John Hope, mechanician, of 14, Water-street, Liverpool, has been kind enough to say that rather than readers of the "E. M." should be misled by such an assertion, he is willing to afford him "ocular demonstration" of the fact at any working hour he may choose to call.—W. H. Davies.

[46089.]—**Muffle Furnaces.**—There is no reason why the furnace described should not be suitable for burning small plaques, &c. All that is necessary is the muffle should be of sufficiently large size to admit the articles requiring to be fired. Large things of the size mentioned you had better get done in a potter's kiln. Should you intend making the furnace, I will send dimensions of the larger muffles.—Arthur E. Morris.

[46109.]—**Hardness of Water.**—Standard solution of soap: 10 grams of pure Castile soap, in fine shavings, are to be dissolved to 1 litre with alcohol of 35 per cent. 1cc. corresponds to 1° of hardness, or ·001 of $CaCO_3$. Standard solution of hard water: Dissolve 1·11 grams of pure dry $CaCl_2$ to 1 litre, with water; or 1 gram of pure marble, or $CaCO_3$, may be dissolved in a slight excess of HCl, and that excess carefully neutralised by excess of NH_3. 1cc. contains lime equivalent to ·001 of $CaCO_3$. As, however, the soap solution is not always correct, it should be standardised by the method about to be described, using 10cc. of the standard hard water, and making up to 70cc. with distilled. Since, however, the distilled water possesses the property of decomposing 1cc., our standard soap solution, if correct, should use 11cc. Supposing, however, it uses 14·5, then, to find what 1cc. of the soap equals of hardness, is arrived at by the following proportion: If 14cc. of the soap solution equals 11° of hardness, what does 1cc. equal? Having obtained a correct standard solution of soap, we now proceed as follows: 70cc. of the water under examination is accurately measured, and introduced into a stoppered bottle of about 200cc. capacity, and agitated thoroughly; then suck out the air from the bottle through a glass tube, so that any CO_2 given off by the water may be thereby removed. Next add 1cc. of the standard solution of soap, shake the bottle vigorously, and repeat the process after each addition, decreasing the quantity of soap-test added from time to time, until, as the reaction is approaching completion, the soap solution must be added drop by drop. When a good froth has been obtained by shaking, the bottle is laid down on its side; and if the lather remains permanent for the space of five minutes, the operation is finished, and the quantity of soap-solution used must be accurately noted. If, however, the lather breaks up before the expiration of five minutes, more soap-solution must be added until the lather acquires the requisite stability. The reason that a lather cannot be produced until a certain quantity of the soap has been used is, that when soap comes in contact with waters containing salts of lime and magnesia, the soluble alkaline oleates, stearates, and palmitates composing the soap are decomposed with the formation of insoluble lime and magnesia salts of the fatty acids. Hence it is impossible to get a lather until the water has been softened at the expense of the soap. If the water is very hard and uses more than 16cc. of soap, an aliquot part of 70cc. must be taken and diluted to that volume with distilled water, since the results are not so accurate with a large quantity of soap. The process is gone through as described, but the number expressive of hardness will have to be multiplied by 2 if 35cc. be taken, or some other figure according to the degree of dilution of the sample. But when noting down the number of cc. used, 1cc. must be deducted from the distilled water used, for the reason above described. When the excessive hardness is caused by the presence of magnesia salts, indicated by a characteristic lightness of the curd, the water should be diluted with distilled water until less than 9cc. of soap are required for 70cc. of the diluted water. The quantity of soap thus consumed is called the "total hardness," but many waters become softer on boiling. This is due to $CaCO_3$, held in solution by the excess of CO_2, hence, when it is boiled the excess of CO_2 is driven off, and $CaCO_3$ precipitated. The decrease produced by boiling is called "temporary hardness," whilst the remaining hardness is termed "permanent." The permanent hardness, which is due almost entirely to $CaSO_4$ and $MgSO_4$, is ascertained by first boiling some of the water (about 200cc. or 300cc.), gently allowing the steam to escape freely, and then, after it has cooled and the loss by evaporation has been made up with recently-boiled distilled water, applying to it the soap-test as before. On no account must the steam from the flask be condensed and allowed to flow back into the boiling liquid, because the condensed water dissolves the escaping CO_2, which is thus continually returned to the contents of the flask in sufficient quantity to prevent the complete precipitation of the carbonate of lime. Hoping I have not made this too long for insertion, if the querist requires a table for the conversion of these degrees into Dr. Clark's, I shall be glad to let him have it.—J. C. Belcher.

[46118.]—**Slide Valve and Piston.**—If you have a good lathe or planing machine handy, take a light cut across the valve face—that is, at right angles to the direction of the valve's travel. Then, if the cylinder face is not badly cut, you can scrape the face to the valve, using a little thin red lead and oil to show the high parts If the cylinder face is badly cut, you must get it planed up by some firm who have a portable planing apparatus for such jobs. On no account attempt to grind the valve and face together. Anything I can tell you I will with pleasure.—Labor Omnia Vincit.

[46158.]—**Ginger Ale**—Is an aërated beverage made in the usual way, but flavoured with soluble essences of ginger and capsicum and essential oils. —R.

[46161.]—**Pumping to Pressure.**—Your idea of an escape valve to supply the reservoir is practical enough, but it is not economical as far as working expenses go. You would have the extra pressure on pumps and main, which would require more steam, and consequently more coal, to do the work. As the supply to 3in. main is but small compared to the other, why not put down a set of force pumps for the high level specially, and drive by a belt from the main engine?—Labor Omnia Vincit.

[46177.]—**Tinning Bicycle Spokes.**—I see no difficulty in doing this. Clean the spoke with number F emery cloth; have a Bunsen gas-burner (ordinary burner would not do, as it would smut the work, and the tin would not stick), with a rubber-tube to feed it. Heat the spoke with this, having previously wetted it with spirit of salts, with a little zinc in it; when hot enough to melt the tin, run a little along the spoke, smoothing it if rough in places with a hot soldering-copper. I have thought of doing this myself to prevent rusting, but have not done so as yet. Would "52in." say how it answers after a month or so's trial? It is very easy to take a wheel to pieces, but quite another thing to put it together again,—about the most difficult thing in making a machine.—Ixion.

[46199.]—**Impurities in Acids.**—Commercial sulphuric acid often contains lead sulphate, and not unfrequently arsenic (which is derived from the pyrites). The lead sulphate is owing to the action of the acid on the leaden chambers in which it is condensed during its manufacture. It also frequently contains nitrogen oxides and sulphur dioxide. The latter may be detected by shaking the acid in a bottle and testing the air with iodised starch-paper. If the paper is turned blue the lower oxides of nitrogen are present, and if sulphur dioxide be present the blue colour will gradually be destroyed owing to the bleaching properties of the dioxide. Sulphuric acid may be purified from lead sulphate and oxides of nitrogen by redistilling it with the addition of a small quantity of ammonium sulphate. The hydrochloric acid of commerce generally possesses a yellow colour, which is due to the presence of either chlorine or ferric chloride. Sometimes, too, it contains sulphurous, arsenious, and sulphuric acids got from impurities in the oil of vitriol used in its manufacture. Nitric acid has a yellow colour, owing to the presence of lower oxides of nitrogen, from which it may be freed by passing a current of air through the acid. Oxalic acid, being produced from nitric acid and various organic substances, often has impurities which are difficult to determine. Some of the oxides of nitrogen are frequently present.—Hugh Tunnadine.

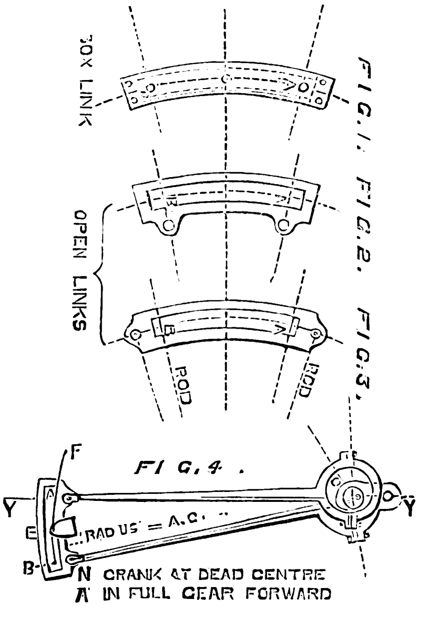
[46202.]—**Pattern Making and Casting.**—To "Cast Iron."—Many thanks for kind offer. A few hints on pattern making for tools and machinery for amateur engineer's workshop, and a little instruction in brass-casting, would be of great service to those who have not back vols. to refer to.—E. C.

[46213.]—**Measuring Steam.**—I have never heard of any kind of meter for this purpose. But it seems to me that the best and fairest way would be for the parties to get some independent engineer to come at stated times, and indicate the engine, and let the price be based on the horse-power exerted. The practice of supplying "room and turning" is common enough in the northern manufacturing towns, and this looks like a similar instance.—Labor Omnia Vincit.

[46217.]—**Model Electric Engine.**—In reply to Mr. Lancaster (p. 16) I would like to make one with power enough to work an American organ. Should like to hear from Mr. Lancaster. I thank "R. W." for his answer.—W. F. G.

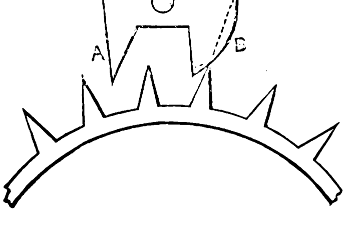
[46220 and 46222.]—**Link-Motion.**—To give "rules" for proportions of link-motion is not quite as easy as "A. B. C." and would require one to write a small book. Besides which, it is necessary to thoroughly understand the slide-valve as well. If, however, you simply wish to use the link as a reversing gear, and are not particular about equalising the admissions at each end of the stroke, the matter is not so very difficult. A small amount of lap will do for reversing; the link should be struck out with a radius equal to the length of the eccentric rods (not straight—that requires a different arrangement). The link may be four times the stroke of the valve in length, measuring from the centre of link-block at its two extreme positions, and it may be hung from one end, by hangers longer than itself, to arm of reversing shaft, which should be arranged in such a position that the link-block will travel up and down as little as possible in working. The eccentric rods should be so connected with the ends of the link that they will be crossed when the eccentrics are both towards it; the head of the slide-valve will then disappear at mid-gear and the reversing lever can be used to shut off steam. If you wish to use the link as expansion gear, you must have a good deal of lap on the valve—one port of lap is a good proportion. If this is not possible, owing to the space between your ports, have as much lap as you can get without throttling the exhaust when the steam-port is wide open. Next let the eccentric rods be crossed when the eccentrics point away from the link, because then the lead will increase towards mid-gear, which is better than losing it in the intermediate gears. To explain how to equalise the admission is difficult without figures; the principle, however, on which it is done may be shortly told. First it must be understood that since the angles of admission are equal, the engine will get more steam at the back end of the cylinder than at the front, owing to the obliquity of the connecting-rod. Moreover, it can be imagined that the slight movement of the block in the link in working will have an effect in shortening or lengthening the admission according as it moves to or from the centre of the link. This movement is taken advantage of by so placing the reversing shaft and its arm that the movement of the block in the link corrects the inequality in the admissions.—F. A. M.

[46220.]—**Link-Motion.**—You may use one of the three forms shown on the annexed sketch. But if I were you, I should prefer 1 or 2 to 3 for these reasons: the extremity of the eccentric rod comes just opposite the stud of the valve rod when your engine is in full gear. No. 3 is perhaps more compact, but requires larger eccentric sheaves. Moreover, the chief difficulties lie in the fact that since the stud of the valve rod is below the extremity of the eccentric rod, you will find it difficult to determine the proper angular advance and throw. They can only be discovered by approximate guesswork, entailing a succession of tedious trials, especially when you have not at your disposal an apparatus or working model to facilitate your researches. Having adopted No. 1 or No. 2, you will proceed to determine, by some well-known method, the angular advance, throw, outside lap, lead and side lap (if any), from the knowledge of the lengths of admission, compression, pre-admission, early exhaust, &c. The unknown elements are found as if you had to deal with a single eccentric. I should strongly recommend the beautiful and general method of Zeuner's polary diagram. Both eccentrics may be set with the same angular advance. The length of eccentric rods is not to be less than 10½ times the throw, or else no methods in use to find the above elements will give correct results, as such methods are based on the fact that when the length of the rods is over 10½ times the throw, this length may be disregarded. We shall, besides, see that in the case of a link it is advisable to have very long eccentric rods. The length of the link marked A B on the sketches seems immaterial. It cannot, however, be too short nor too long. If it is too short, the amplitude of its oscillations is greater than is necessary, and the stud of the valve rod works hard, and this would be noxious to the regularity of the movements of the slide. A good proportion is from 0·8 to 0·9 of the diameter of the piston. This limit ought not to be exceeded, as otherwise an over-long link will impair the working of steam in the cylinder, as will be explained hereafter. The radius of curvature of the link is equal to the length of the eccentric rods. This condition it essential. When this radius of curvature is not made equal to the length of the longest rod, it will be difficult to insure equal leads for each side of the piston and for each notch of the sector. As to the suspension-links, they can be indifferently connected, either at the middle, or at any one of the two extremities of the link; care must, however, be taken to make the suspension-link as long as can be done. The distance of the suspension-link's extremity connected with the tumbling-shaft from engine-shaft, is equal to the length of eccentric rods, minus the *versed sine* of the link's curve. Had you given us the dimensions of your steam-ports, and conditions under which the steam has to work the piston, I should have been pleased to work out the design of your link, and show how to proportion its different parts. Fig. 4 is a skeleton sketch of link, No. 2, often in use. O is the centre of shaft. O C = O D throw of eccentrics. C A = C B vertical length of eccentric rod. A B = chord of curvature of link. No important error would arise from substituting the length of this chord for that of the arc. The link is suspended at E by the link E F, the distance of E from O Y is equal to C A — *versed sine* of arc A B. The radius of curvature of A B is equal to A B; the centre is about D, but the smallness of the sketch could not allow me to mark it neatly. Concluding remark: I have said before that the link must not be too long. It is shown by practice and theory that the lead increases as the link is lowered (this is only true in the case of open rods, as in Fig. 4). But for all that, the opening of the steam ports is getting less and less. The cut-off begins early, and the expansion is long. It is the same, of course, with compression. These two occurences are detrimental to the working of the engine. They are more marked with short eccentric rods. Avoid them, and as much as as possible, try to get long rods, so that the length of the link will be short when compared with them. See the most recent four-coupled engines on the M.R.; the links are placed beyond the motion-plate; such a distribution is generally found to work regularly. It is perhaps more for the purpose of being enabled to reverse the motion than to have the advantages of the cut off, that you want to fit your engine with a link. Still, I should advise you not to disregard the observations given above, as you will lose nothing by being a little at the trouble of setting accurately your valve-gear. If your steam-ports are relatively shorter but wider than they would be in a locomotive, I should insist chiefly upon long rods and a short link.—Ed. Gobert, B.Sc., Nottingham.



[46224.]—**Silver Solution.**—I do not wonder that J. M. Stocks got a "dirty mess" by introducing a few drops of CS_2 into a plating solution. The instructions in Gore's "Electro-Metallurgy" are as follows:—The brightening effect is produced by attending to the following directions: Take one quart of ordinary cyanide of silver plating liquid, old liquid by preference, containing 2lb. of cyanide of potassium per gallon; add to it 4oz. of strong liquid ammonia, 4oz. of bisulphide of carbon, and 2oz. of ether, and shake it occasionally. After it has stood twenty-four hours, add two ounces of the supernatant liquid to 20 gallons of ordinary silver plating solution, with gentle stirring, every alternate day. Or add it every day during the morning in summer, and evening in winter. But in every case it is highly important to add only the least possible quantity necessary to produce the effect, for a greater number of silver plating solutions have been spoiled by addition of an excess of brightening liquid than by all other causes put together. If too much "bright" is added the plated articles become of a brown colour, and frequently spotted. The bisulphide of carbon mixture gradually becomes black; it may stand an indefinite length of time, and as 2oz. of the supernatant liquid is taken out, an equal volume of old plating solution, strong in cyanide, or a strong solution of cyanide alone, should be added; this gradually decreases its blackness, and also prevents its producing a precipitate when added to the solution in the vat.—Sydney H. Holden.

[46234.]—**Drum Timepiece.**—The French drum timepiece is universally voted by the trade a perfect nuisance. The principle on which the escapement is constructed is unsound—the impulse being given only from one pallet (*a*). The best remedy I can suggest is the alteration of the resting pallet (*b*) to the form indicated by the dotted lines in the accompanying sketch. Frequently, the cause of stopping is the wearing flat of the back pivot just above the pendulum. This, of course, increases the friction, and stops the clock. In such a case file the pivot to a V shape, commonly called a knife-edge: this will give it a light action. Should neither of the above suggestions avail, the only remedy is new pallets to take over three or four teeth.—C. H. Spurge.



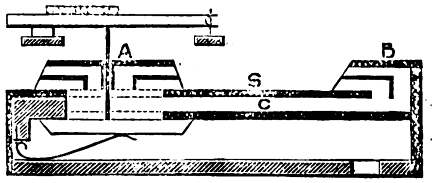
[46286.]—**Geneva Watch.**—Near balance in plate is a screw with half a head; move this just enough to allow watch to pass from front. Be careful to keep balance from contact with side of case, or cylinder will be broken. Be sure not to forget this in putting back movement to case. Ascertain if mainspring is wound; if so, put a small bristle in 'scape-wheel to prevent watch running down when cock and cylinder are being taken out; unscrew cock, and gently prise it up with tweezer's point; take cylinder out of 'scape-wheel teeth, also steady-pins out of plate. After these are loose on plate take them away, holding top and bottom of hairspring stud with tweezers, balance between. Take off hands with a good pair of pliers, and face by unpinning—if screwed, by half a turn to the screw holding it. After face is off, take out hand-wheels; minute-hand pinion can be taken off by a smart tap on end of set-square, where the minute-hand goes on, and is finally taken out by pulling the set-square at back. Now remove bristle, and let spring run down; after which take out all cocks one by one, and keep each screw, wheel, and cock separate, or difficulty may occur in putting together. Get a moderately stiff brush, some good chalk, and after cleaning off all grease with benzoline, brush with a circular motion, using as little chalk as possible; brush the wheels and plate; clean pinions with a bit of cork cut wedge-shape, and holes in cocks and plate with peg. After plate, cocks, wheels, pinions, &c., are all clean, put them back in their places. We now come to the cylinder: examine this with the cock, and it will easily be seen how to take them in pieces; clean cylinder inside and out with elder-pith, and cork cut to a point; take out jewels and clean with pith. The cock jewel comes out by removing the two small screws underneath; the cock holding bottom jewel should be unscrewed before cleaning the plate, and put back after plate is cleaned; this jewel is in a brass setting, and is screwed with one screw under cylinder. In putting back cylinder and cock after they are in place, be sure the hairspring is flat, and does not rub anywhere; also be sure the outer coil is exactly between the regulator-pins when they are in any position, or the watch cannot be regulated to a nicety; put one drop of oil to each pivot with a fine blunt-pointed needle; also one small drop on 'scape-wheel teeth.—Skip.

[46295.]—**Paralysis.**—Your friend has undoubtedly been attended by medical men who know nothing, or, at any rate, very little of the case in question. Paralysus of the legs is a disease which cannot be cured without the help of an experienced surgeon, and it is quite impossible for you, although you might do him good for a short time with the machine you speak of, to enable him to regain his walking powers. I know a friend who once suffered severely from the same complaint, and who has been successfully cured within the space of eight months by F. Graham Bennett, M.R.C.S. and L.S.A., 7, Hertford-street, Mayfair, London, W., to whom he was recommended, although despaired of by other medical men.—Lennox Moore, Cambridge.

[46296.]—**Harmonium or Organ.**—Thanks to "D.," but being a public person, and only making my own instrument by way of amusement, I shrink from advertising my address—willing, nevertheless, to give it to "D." in any private way. Does "D." misunderstand me? I did not intend to make combined pressure and exhaust instrument. My question is, Which of the two is best? Doubtless the wind admitted to the American reed by the cell measuring it explains one great reason for purity of tone—not forgetting the bend, of course. Holding this theory, I intended to turn my 2-row American soundboard upside down, on to pressure-bellows, putting the usual harmonium-pallets on. And for the other 2-row, I had thought to use a harmonium-pan with bent French reeds. But how to put extended pallets for this 4-row I could not see. Before passing judgment, will any gentleman possessing a harmonium open up his instrument and try the effect of a few cells placed over the reeds. To intending A. O. builders I commend "Elève's" instructions for improvement of bass by the additional depth of windchest at that end. I have made my own instrument 1¾in. at bass end, and with sub-bass reeds bent and twisted too, I have got a tone so pure and rich that it is really superior to many "subs" of the best makers. "Saul Rymea," "D.," "Organon," and other gentlemen of the wavy ether—venerated offspring of the ancient Jubal—shall we press you to speak, or shall we exhaust your patience?—Beta.

[46296.]—**Harmonium or Organ.**—In a harmonium containing four rows of vibrators, the pallets should be made of sufficient length to cover all the pallet apertures belonging to each key, but the leather covering the pallet should not extend the full length of it, but only where it covers the pallet-holes. By this means the pallet will be better and the leather on the pallet will bed nicely over the pallet-holes. The pipe-like quality of tone, which is to be found only in the American organ, cannot be produced by a reed-organ constructed on the harmonium principle. In the American organ, the reeds are thinner than those of the harmonium. This characteristic, combined with the suction principle of drawing the air downwards through the reeds, and also the manner in which the reeds are voiced, produces the much admired pipe-like quality of tone. If my advice is of any use to "Beta," I would suggest that he should construct an organ on the suction principle, having four rows of vibrators as follows:—One set of 16ft. reeds of five octaves, one set of 4ft. reeds and two sets of 8ft. reeds. By this arrangement the following stops could be introduced: Bourdon, Baritone, Principal, Diapason, Bassoon, Flute, Dulciana, and Hautboy. An octave coupler added to the above would greatly increase the power and beauty of tone of the instrument.—G. Fryer.

[46296.]—**Harmonium or Organ.**—I send the inclosed rough sketch as my idea of the easiest way to alter a 2-row instrument to a 4-row, or larger. As for turning the present arrangement upside down, what do you expect to gain by it—improved tone, or simplicity of construction? From what little I have seen or heard, you will secure neither. If your present board is an ordinary recent make, you will find that there is sufficient room above middle C to add 2 half-rows, as at Fig. A, which will enhance its capability very much—viz., ½ set of 8ft. pitch to form celeste tone with your present 8ft., and, of course, as solo as well, and ½ set of 16ft. pitch voiced, say, oboe, without disturbing any part of the action. If you decide on doing so, put the celeste set on the opposite hand to your present 8ft. I have treated two boards this way with good results. If, however, this should not satisfy you, add two complete sets at the back of your soundboard, either in the ordinary style, or one above the other, as shown at B, which is more get-atable. In this case you will have to remove your pallets, and put a set of channels across the underside of the soundboard, as shown in the cut (C); about ¾in. deep will do, which will, of course, increase the depth of the windchest, but the same pallets will do, and you would only require a fresh set of pitman rods; and you may even make them do if you have room to lower your keyboard as much as you put to the depth of your windchest. If you look at "Elève's" drawings (by the way I wonder where he is—I owe him a debt of thanks), you will see how the sub-bass is arranged with an extra pallet; this, perhaps, would suit you better, but it means more careful workmanship, and a nasty touch if you are not pretty well up to it. I expect your chief difficulty will be the tube-boards, if you want anything differing from the shop ones; should you make them, I could perhaps give you a hint or two. I have in hand now, nearly complete, a two-manual, with 10 registers, which I have made throughout. I intend to send a set of drawings of same, if our editor thinks them suitable.—Joiner.



[Please send.—Ed.]

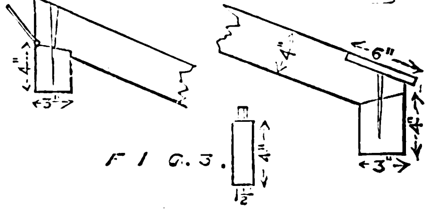
[46309.—**Filter.**—Water filtered in the way stated is good enough for washing, &c.; but scarcely so for drinking, as it usually tastes "flat." If you could give the effluent from filter a good fall to the tank you would greatly improve its taste. Charcoal is considered a better filtering medium than sand.—Labor Omnia Vincit.

[46309.]—**Filterer.**—The water would be quite good, especially if off slate roof. Have used water stored in stonework cistern for years, and some time since had a portion analysed by a first-class analyst, whose certificate runs thus—"from the almost total absence of minerals, and the small percentage of lime, it is fit for every domestic use, being simply equal to soft water."—West Glo'ster.

[46310.]—**Water Supply.**—It is not practicable to get a siphon to work under the circumstances stated. If you cut through the hill I doubt if you would get any supply then through a ½in. pipe with 1ft head.—Labor Omnia Vincit.

[46310.]—**Water Supply.**—On reading this query I was at first inclined to say that it would be impracticable "to get a siphon to work with 1ft. of fall through a ½in. pipe half a mile long"; but on further consideration I do not see why it should. If the pipe be filled upwards from the two ends, and all the air driven out at the highest point, and if a perfectly-fitting air-pump be placed there, and if all the pipe-joints are perfect, there might be delivered at the end of the pipe 100 gallons in 24 hours. That is as much as would flow through a pipe so small and so long, and possibly the flow might cease, even though it begins again; and in any case it would be necessary frequently to withdraw the air, which would accumulate at the air-valve. The best way would be to continue the end of the pipe downwards into a well, 10ft. or so, and pump the water out when wanted, because even if the quantity above named would flow through the pipe, it would run so slowly that it would be unsatisfactory to draw it from a tap. There would be no advantage in cutting through the hill to lay a ½in. lead pipe; but great advantage in doing so to lay a larger pipe, of cast iron, or even of earthenware, if the joints be made watertight; in which case more water could be got through even with 1ft. of fall.—Charles Slagg.

[46313.]—**Roof for Lean-to Hothouse.**—I have built two without help, one 20ft. long by 15ft. wide, the other 7ft. wide, but longer. I recommend pitch-pine, for the reason that, even if not kept well painted, it does not decay. My rafters are 4in. by 1½; they are tied together by two angle-irons, 20ft. by ¾ of inch (in shape of letter L), and about 5ft. apart. The last time I painted the roof I took the precaution of supporting it by procuring some lengths of second-hand, and discarded iron gas-pipe at the price of old iron, one to each alternate rafter, standing them on bricks and mortar 9in. square. If I built another I would have the rafters 5in. by 1½, and no supports. The "plates" front and back are 20ft. long, 4in. by 3. There should not be any horizontal ledges to hold condensed water. This is most important. Fig. 1 shows how the rafters are fastened at back; the iron spike 7 or 8in. long, the slope for draining top of plate, and the ventilator between rafters to be closed by wire and bell-crank, and pushed open with a stick. Be careful to use two sizes of carpenter's bits in boring, or you will split the wood. Fig. 2 shows how the rafters are fastened in front—the spike and slope of plate to get rid of condensed water, and the piece cut out of all the rafters, and section of a piece of wood 20ft. long, 6in. wide, ½in. thick, to carry water to spout; the first piece of glass overlaps this ½in., the remainder should only overlap each other ¼in. Fig. 3 shows section of rafter, with strip of wood ¾in. high and ½in. wide nailed on. The advantage of this way is, that if the rafters are not quite straight, or perfectly equidistant, your bead will be, if nailed on the last thing before glazing; 20in. is a nice medium size for width of glass. You need not make any allowance for expansion; do not overlap the glass in front or end, it makes a nasty green mess; if the butt ends of glass are brought together, it is as tight as a cracked pane, tighter than an overlap. The house, 7ft. wide, has rafters 3in. by 1½in. This is ample. Give one coat of paint to every piece of wood before nailing it in place. This will preserve from getting saturated and warping while the job is about, and make all your joints much better.—Gamma.



[46318.]—**Protecting Steam-Pipes.**—If you cover a steam-pipe 1in. diameter with 1in. of Leroy's non-conducting composition, you will certainly prevent condensation. If you cover a water-pipe with the same, the frost, even in Canada, will have no effect on the water inside.—One who has Experience.

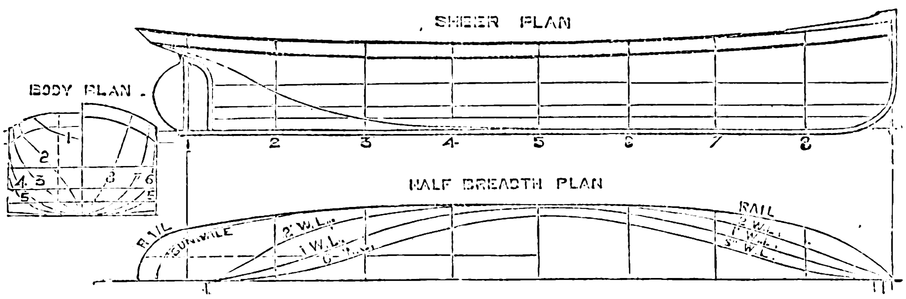
[46319.—**Engineering.**—"Inquirer" can see any number of self-acting inclines in work at Portmadoc or Festiniog, but none so flat as 1 in 10, although such a one would work if, say, the first 20 yards were made much steeper, say 1 in 4 or 5. Much depends upon the weight of the rock to be conveyed. Owing to the great length of the incline and its flatness, it would be better to divide into two, or else run a part of the distance level, and so increase the rate of gradient.—D'Elgo, M.E.

[46319.]—**Engineering.**—If "Enquirer" will come to my address he can see exactly what he requires, and inclines such, as I do not think there are elsewhere in England. He can then carry out what he wishes. Some of our inclines are one in three. Should "Enquirer" find it convenient to come here he might drop me a post-card, stating what day I might expect him, and I will arrange to be at liberty to show him our inclines and give him all the information in my power.—Chas. Anderson, Resident Manager, 22, Battersby Junction, viâ Northallerton, Yorkshire.

[46321.]—**Tipping Clay Tobacco-Pipes.**—Construct a small coke furnace, with an elongated aperture a few inches above the fire-bed, so that the stems of the pipes may be inserted; then get up a white heat with coke and the fire is ready for use. Next mix a portion of red-lead in water and stir till it has the consistency of cream, after which it must be brushed on to the tips of the pipes, shake off the superfluous drops and place the stem-ends of the pipes in the furnace for a few minutes. When they have attained to a dull white heat they must be instantly withdrawn, and the ... bulbs shaken off whilst hot; on cooling they are ready for use. Red-lead alone gives straw-colour; but greens may be obtained by an admixture of solution of copper; browns with the addition of oxide of manganese; orange, with a solution of bichromate of potash, mixed amongst the lead-water. A hard varnish may be got without the use of fire with a mixture of methylated spirit and shellac, which dissolves at once, and may be coloured to any shade with pigments; but it is not so efficient as the lead-glaze.—George Hamilton, 8, Riley-street, Cromer-street, W.C.

[46327.]—**Steam-Launch.**—"Dow" does not say what kind of a launch he would like to have. The size of his boat would depend greatly on the weight of his engine and boiler, and the duty it is intended to perform. The breadth should be about 6ft., or one-fifth the length. The depth should not be less than 3ft. 6in. If he likes to be particular in setting off his frames, he should lay them off on a small drawing on paper, say, to a 1½in. or 3in. scale, and work this off on the scrive-board to its true size. From this he could work from.—Chippy.

[46327.]—**Steam-Launch.**—I send lines of one 30ft. inside of post to inside of stem, 6ft. 3in. extreme breadth, 3ft. 6in. from top of keel to rail: scale ⅛in. to the foot. In setting off the frames, it would be better to lay it down on a larger scale. If your frames are 1in. by 1in. angle iron, 21in. or 24in. apart would do. You will see by the plan how the frames are set off.—W. A. S. Shields.

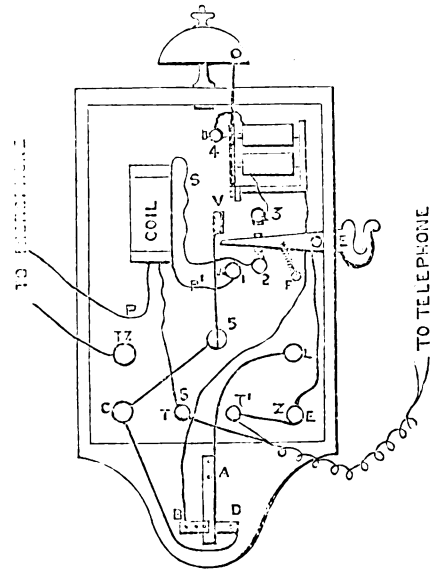


[46333.]—**Gregorian or Cassegrain.**—There is no difficulty in replacing the metal mirrors by glass ones, except that opticians don't seem to care to make them of the short foci required for such a telescope, probably 2ft. focus the large mirror, and 4in. or 6in. the small one. The mirrors must, however, not be spherical, or they will be useless. By fitting it up as a Cassegrain, a mirror of longer focus could be employed, which is an advantage; but the small convex mirror is more difficult to get made true, than the small concave of the Gregorian, though when true, it is freer from aberration, or rather renders the combination freer. The cost on either system would be about the same, say, £5 10s. to £6, and I think the money would be better expended on a Newtonian mirror. The old stand he might perhaps sell.—C. N. R.

[46334]—**Purifying Gas.**—"Rosicrucian" should have given more particulars about this mode of purifying, if whether the ordinary dry lime method or otherwise. However, assuming they are simple dry purifiers, there should be eight sieve-plates—seven for holding lime, and one for crushed coke. This one, placed next the inlet, should have a ¾in. mesh, and ordinary gas-coke in lumps, only large enough not to fall through, should be laid on all over, about 3in. deep, the object being to spread the gas evenly over area of purifiers before coming into contact with the first lime sieve. It will also absorb what small amount of tar and ammonia there may be left, and prevent the incrustation of first sieve of lime, which, without the coke, would harden and prevent the passage of the gas. Each purifier should have clean coke once in two months; it is quite as essential and useful in purifying as the lime itself. The lime must be slaked, and sifted through a ½in. mesh, laid lightly and evenly on perforated sieves, and should be slightly damped, but not made wet enough to get hard, or you will have trouble. For testing quality of light refer to "Ours" of Feb. 3rd, page 525, query 45794. The simplest test for sulphuretted hydrogen that I know of is as follows:—Take as much acetate of lead as will lie on a shilling, place in a saucer one-third full of water; when dissolved, take a piece of writing-paper, dip this in the solution, and hold over a gas-jet, not lighted, inserted in main between purifier and gas-holder. If no discolouration takes place the gas is right; but if it turns black it contains impurities, and should be at once seen to. With regard to the best coal for gas-making, you must remember there are no two samples alike, either for quality or quantity; and if you can get an 18-candle gas at, say, 10,000 cubic feet per ton from your home coal, you cannot much improve matters unless you mix a little cannel with it; but do not use all cannel, or you will have to purchase coke. I have had the anti-dip valves at my works for some years. They are worthy the attention of small works' proprietors, giving, by relieving back pressure on retorts, quite 1,000 of gas per ton of coal.—On Guard.

[46336.]—**Telephones.**—I shall be much obliged if "T. C." will give me the promised information. There is one home-made telephone at either end, each of which in turn transmits and receives. One wire is stout copper insulated; the return is galvanised iron not insulated. Is this correct? I shall also be obliged if Mr. Lancaster, in reply to same query, will say how microphone should be added to telephone.—Meme.

[46336.]—**Telephone Circuits and Call.**—The rough sketch I send will explain how to make all the connections. This one is the same as supplied with the Blake's Transmitter, and is as simple as any I am acquainted with. You will notice the hook E has the telephone off, the spring F has drawn the hook contact down on contact 2, S¹ is the secondary wire of the coil; a current coming from S¹ passes through contact 2 into hook to B through contact to A to terminal L, this being line. The other end of secondary, S, is fixed to terminal T; T¹ is connected to terminal Z E; zinc of battery and earth is connected to terminal Z E, hence the two letters; the telephone cord is connected to T T¹; the primary wire of coil, one end P to microphone, the other end P¹ to contact 1; T Z is terminal of transmitter zinc; C is terminal for copper or carbon end of battery. When the telephone is on the hook it draws it down and places hook contact in contact with bell contact 3. A current now being sent from the other end to ring up, passes through L A B to 3 through bell coils, regulating screw 4 through keeper and frame to Z E. The act of taking off the telephone allows the hook to slide off the vulcanite V, and lets the ring 5 come in contact with contact 1; this puts C in connection with one end of primary P, the other end P¹ was already in connection with T Z through the microphone. The instrument is now ready for speaking to. A current now coming through line passes through A B hook 2, secondary wire to T through telephone cords, coil, T¹ to Z E. To ring up A is pressed on D; this does not affect your own instrument, as A leaves B before it touches D, so cut your own instrument out. Shall be willing to give you any further information.—George Tolman.



[46352.]—**White Fungus on Fish.**—A paper appeared in *Science Gossip*, No. 186, June 1, 1880, on "Salmon Disease, and its Cause." This may give "C. O." the information wanted. Personally, I have recovered gold-fish attacked with *Saprolegnia ferax* by isolating those diseased; placing each subject in a shallow vessel of water, and sponging lightly over with silver-sand two or three times daily, changing the water each time.—J. C. M.

[46355.]—**Photo-Enlargement.**—If "H. C. F." can get his glass negatives to fit into the magic-lantern, he might be able to obtain very fair enlargement on Morgan's argento-gelatino-bromide paper, which is the most simple and efficient article he can use. First thoroughly darken the room, and use only a red light to work by, and screen any white light that may be reflected from the lantern; then place the negative in the lantern and focus it upon a sheet of clean paper placed upright against a flat surface (a very good way is to moisten the paper and fold the top edge over a sheet of glass and stand it upright against the wall on a table). When the picture is clearly defined, and of the desired dimensions, cover up the front lens of the lantern, or place a screen of red glass between it and the image; then, having moistened a piece of Morgan's paper in clean water to make it lay flat and smooth, substitute it on the glass sheet for the piece of ordinary paper used for focusing, and remove the screen from the lens, when the image will be clearly focused on the sensitised sheet. Expose for three to five minutes, according to amount of light; then remove and develop with a ferrous-oxalate developer, until the picture is well defined; then wash and fix as for a gelatino negative. Practice alone will give experience, and experience efficiency.—F. C.

[46356.]—**Analysis of Alloys.**—If only the metals named are present the following method will serve to separate and estimate them:—Heat a known quantity (2 or 3 grams) of the finely-divided alloy with strong nitric acid until all action ceases, then dilute and filter. The precipitate will contain all the tin in the form of metastannic acid, and nearly all the antimony in the form of antimonious and antimonic oxides. Wash it on the filter, transfer to a silver dish, and fuse it with excess of pure sodic-hydrate, by which it will be converted into a mixture of sodic stannate, and sodic metantimoniate. On treating the mixture with dilute alcohol, the sodic metantimoniate remains undissolved, and may be collected on a filter, washed with alcohol, dried, fused with potassium cyanide in a porcelain crucible, and the reduced antimony detached and weighed. The alcoholic filtrate is boiled to expel the alcohol, diluted, acidulated with sulphuric acid, and precipitated with hydrogen sulphide. The tin sulphide is collected on a filter, washed, dried, and converted into stannic oxide, by careful roasting in a porcelain crucible, and weighed. The nitric acid solution will contain the copper, zinc, and iron as nitrates, together with a little antimony. It is evaporated with excess of dilute sulphuric acid, to expel nitric acid, diluted and precipitated with hydrogen sulphide. The precipitate containing the copper and antimony as sulphides is digested with a solution of potassium sulphide, and filtered. The precipitate is washed, dissolved in nitric acid, and the copper precipitated by sodium hydrate, and weighed as cupric oxide. The antimony present in the potassium sulphide solution is precipitated by adding excess of hydrochloric acid, converted into tetroxide by treatment with fuming nitric acid, and subsequent ignition in a porcelain crucible, and weighed, the amount obtained being added to the main portion already determined. The filtrate containing the zinc and iron is boiled to expel the excess of hydrogen sulphide, and then, with a few drops of nitric acid, to peroxidise the iron, nearly neutralised with sodium carbonate, mixed with a small quantity of barium carbonate, digested for a few hours in a corked flask, and filtered. The precipitate is dissolved in dilute hydrochloric acid, and the iron precipitated with ammonium chloride and ammonium in excess, washed, dried, ignited, and weighed as ferric oxide. The filtrate containing the zinc is mixed with ammonium chloride, precipitated with hydrogen sulphide, the precipitate dissolved in nitric acid, and reprecipitated by sodium carbonate. The zinc carbonate is then filtered off, washed, dried, ignited, and weighed as zinc oxide.—Analyst.

[46360.]—**Roofing.**—The best slate to be had for love or money is the new quarry, Velinheli, size 20 by 10, on 1½in. by ¾in. laths, spiked by two 1¾ copper nails to each slate. Seconds quality, these slates will cost in London about £8 15s. 6d. per 1,000, of 1,200. Price per 100 square yards, labour, laths, and nails included, £13. You should get it done for this sum, and if unable to get these slates, let me know, and I will help you. If properly done, there needs no felt at all; but if you must felt, why, then, there is no better material to go under slates; but I cannot recommend it. If Portmadoc slates are used, it will cost, labour and all included, £9 18s. per 100 square yards. These are good for exposed situations, as they lie evener and closer. Cost at quarry, £5 10s. per 1,000 of 1,200, and weigh 2tons 10cwt. per 1,200.—De Lisle, Contractor and Builder.

[46365.]—**Income-Tax.**—I am obliged to Mr. Wetherfield. I see his meaning, but the difficulty is this: the tenants pay Schedule A, and I am bound to, and do, allow it out of the rents, therefore, if I pay on pension and appointments, I should be compelled to appeal each year to get back that paid on ground-rents, or put up with the loss. I may mention that I have not been asked for a return for three years, and the last time I did not show the rents, as I was told my return was too honest—it was already paid; but the contention of the Surveyor is that I must pay on the appointment, no matter if the income is under £150. Is that so?—J. W.

[46368.] — **Clock.** — You must unscrew the winder; turn the opposite way you wind, and it will come off; also take off the hand-setter; you must pull it off—it does not screw; and you will find the back free.—Escapement Maker.

[46368.]—**Clock.**—To take off back, turn winder in opposite direction to that of winding, and it will unscrew; take off hand-setter with pincers by a straight pull. To remove back, press fingers on, and, with a slight turn, it will unhook. If screws are out of front, the movement is now out of case. If "Anxious Amateur" wants to clean his clock, he must begin by first measuring how far balance-spring comes through stud, and be sure he puts it back in same place. Take out wedge which holds spring in stud; also take spring clear out of regulator, and remove one screw, supporting balance-pivots, and balance with spring are now free. Before going farther, let down mainspring by tying 'scape-wheel loosely to frame; remove pin or screw in pillar nearest pallets, and carefully pull apart frame, which will let out pallets; but be sure no other pivot gets out of place, or the clock will go to smash. Another way to let down spring is to withdraw click from ratchet after putting winder on, and letting it down by half-turn each time, and replacing click; but the first method is least dangerous, if my instructions are carefully attended to. Should the clock be too dirty to run down, put a little oil to pivots.—Skip.

[46370.]—**Lathe.**—Get the holes cast in the standards a free fit; get the two slide bars accurately turned, with shoulders to bear against the standards, or the lathe will certainly vibrate. Tap the ends, and put on double nuts on do.; when adjusting for parallelism, bring true with pegs of wood in holes, then place a band of loam round each side, and fill up with Babbit's metal, or block tin alone. This will make all secure. The screw is best placed between the bars, as giving a more direct pull to saddle. Neither the leading screw, nor those appertaining to the slide-rest, will admit of being screwed with a "screw-stock," they must be chased up, as an inaccurate screw-lathe is an absurdity, and no screw of any length can be made to approach accuracy in a screw-stock. The nut for leading screw ought to open in two pieces, *à la* Whitworth, and you would do well to get the getter-up of your slide-bars and screws to make this also, and as for the slide-rest, unless you are possessed not only of a larger gear, a larger amount of experience, and the most liberal supply of gold, don't undertake it. The very patterns would cost more than you could buy one for. You "must" chase the thread upon the mandrel with a comb. I would strongly recommend you to have either a beech "shears" plated on top and sides, or, better still, a cast-iron one instead of shaky bars, which would vibrate were they 1½ diameter, if such a diameter of face-plate and work were attempted.—J. J. A., Liverpool.

[46372.]—**Classification of British Beetles.**—"A Lady Entomologist" will find "Pye's British Beetles," (published, I believe, by Longmans, at 10s. 6d.), a very useful book on the classification. If, however, she wants a more exhaustive work, "Cox's Handbook of the British Coleoptera" (Janson's, 17s. 6d.), is the best book at present published.—Coleopterist.

[46373.]—**L. and S.W.R. New Coupled Bogie Express Engines.**—There are 13 of these engines. They number from 135 to 147.—Gem.

[46374.]—**Gauging Water.**—In Box's "Hydraulics" is a table of the flow of water through a notch-board 1in. wide, and at depths varying from ¼in. to 125in. This would suit you, I think. Labor Omnia Vincit.

[46375.]—**Steam Trap.**—For compactness and certainty of working, I have not found any trap tetter than Vaughan's Ejector. All steam-traps I have ever seen require cleaning out at times.—Labor Omnia Vincit.

[46375.]—**Steam-Trap.** — I have had several years' experience with Oxley's steam-traps, and they do their work very satisfactorily. We have steam-pipes from boilers at bank to engines underground, 48 fathoms, and, of course, there is a great deal of condensation of steam, the pit being cold and pipes uncovered; but Oxley's steam-trap keeps us all right. They are a good deal employed in this (Cleveland) district, and, I think, give general satisfaction.—Brakesman.

[46376.]—**Weight of "Grosvenor" (No. 151, L.B.S.C.) Empty:—**

	Tons.	Cwt.
On leading wheels	10	8
,, driving ,, ...	14	0
,, trailing ,, ...	8	12
Total weight empty....	33	0

The tender holds 40cwt. of coals and 2,520gal. of water. The total weight of engine and tender in working order is 59tons. I have not the weight of the "Terriers," but will endeavour to obtain them. Sections and elevations of the North British engines appeared in Vols. XLV. and XLVII. of *Engineer*, but their weight was not given.—Meteor.

[46377.]—**Electric Motor for Tricycle.** — I am making one, and the weight is about 60lb. I calculate eight Bunsen or Grove cells of large size will propel it on level road, I should think, six or eight miles per hour. A smaller motor and less battery power is advisable to propel it a little. This would make it equal to level road the day through, and would perhaps avoid the "Locomotives" Act. George Tolman.

[46390.]—**Turning Cotton Calender Rollers.** "G. H." requires a scraping tool for reducing ends of calender rollers, which should be made out of steel 2in. broad by ⅜in. in thickness and about 8in. or 9in. in the flat part, with a shank forged down to fit into a handle about 1ft. in length, so as to make up a tool about 18in. long. The nose of the tool should be ground quite square, and cutting edge should be a slight curve to prevent corners digging. Twenty-five revolutions per minute would be quite sufficient for speed. A temporary rest may be formed either out of 4in. square timber hard wood or a piece of iron bar held by suitable brackets bolted to the chucks of the calender. Either cotton, paper, or brass bowls may be trued up in this manner. If the metal roller in contact with the cotton has a good even surface, use water while scraping, and it will show when the ends are sufficiently reduced by the middle portions of the roller becoming dry.—J. Rawlinson.

[46395.]—**Gilding Watch Plates.**—To make watch plates have the frosted appearance, take 2½ nitric acid, 2 muriatic acid, full strength. Dip the articles for a few seconds, rinse in water, use scratch brush with a circular motion, and then gild. —Pivot.

[46397.]—**Slide-Valve.**—If "Wykehamist" is a resident in the old city from which he takes his signature, he can have the subject explained and illustrated to him any day by taking a walk down the meadows to the Corporation Sewage Works, where he will see the same kind of valves he writes about. For the information of others, I may say that there are two sets of valves, one called the main slides, working against cylinder-face, and the other the expansion valves, which slide against back of main valves. Each set is worked by a separate eccentric. The main valves have a steam-port at one end, and are not moved to alter the cut-off. This is done by a right and left-hand screw on the expansion valve-rod, so that whichever way the hand-wheel on end of valve-rod is turned, the expansion valves move over the steam-port in valve sooner or later as the case may be. These valves are used in other kinds of engines, as well as beam-engines.—Labor Omnia Vincit.

[46404.]—**Medical Battery.**—Do you require a battery of 20 or more cells, or is it a coil and battery; the latter has been described in "ours." You could purchase a set for less than the cost of materials.—George Tolman.

[46405.]—**Stains on Dry-plate Negatives.**—(1) Immerse the plate after fixing and washing in a bath composed of alum 2oz., citric acid 1oz., water 10oz., or in water slightly acidulated with hydrochloric acid. Prevention, however, being better than cure, dissolve a few grains of sulphite of soda in the developer. This prevents its rapid discolouration, and thus staining of the film is avoided. (2) There is no reliable method of effecting this much desired restoration.—Baboon.

[46405.]—**Stains on Dry-plate Negatives.**—A saturated solution of alum with one drachm of hydrochloric acid to about five ounces, is about the best thing for pyro-stained negatives. I think if "J. L." mixes fresh developing solution as soon as the first discolours, he will not be much troubled by stains. I have never heard of any way of renewing faded mercury intensified negatives. Have tried, but only fogged the plate all over, or cleared away all traces of picture.—E. F. C.

[46405.]—**Stains on Dry Plates.**—"J. L." does not state the kind of stain on his negatives. Let him immerse his unvarnished plates in a solution made of one pint of a saturated solution of alum, to which has been added 2oz. of citric acid. This may remove the stains. Some stains are easier removed by soaking the plate in a weak solution of hydrochloric acid. Some negatives that have faded to a yellow by the injudicious use of mercury may be restored by removing the varnish and dipping the negative in hyposulphite of soda. —W. T. Bashford.

[46408.]—**Copper Salts.**—You do not say definitely what you wish to do. Do you want to precipitate copper from a solution of its sulphate by means of zinc? If so, no bath of "double salts," which, by the way, I do not know what their composition or use would be, is needed. Place a piece of clean zinc in the solution; copper will be precipitated, an equivalent of zinc being dissolved, forming sulphate of zinc. The finely-divided copper can be afterwards washed and dried.—Arthur E. Morris.

[46409.]—**Sulphuric Acid.**—As you ask about the factor used by Dr. Ure to estimate percentage of H_2SO_4 from the sp. gr., I have sent it. Multiply the logarithm of the sp. gr. by 350; the product is exactly the percentage of acid. Should you wish it, I will send table showing the percentage of H_2SO_4 in solutions of various sp. grs. and also showing degrees of Baumé and Twaddle.—Arthur E. Morris.

[46412.]—**Pendulum Spring.**—To "Nicholls." —To get spring from collet, take off collet from balance with a sharp pocket-knife, put collet on a tapering piece of pegwood, or anything round, that you can press the collet on firmly; then take a very fine needle, and press pin out of collet (with needle), and balance-spring will come out easily. To cut off inner end, lay spring flat on a piece of clean note-paper, take a pair of fine-pointed tweezers in one hand, and anything with a point in the other, and break off bit by bit till you have broken off sufficient to admit the collet freely; but first you want a spring the proper size and strength. To get the size, put a spring rather less than your old one (which you say is too large) between the curb pins, and balance spring stud as if you were setting the watch in beat; after you have pinned in the spring, see that the second outer coil does not touch the inner curb pin or the stud, and that the centre of the hair-spring is exactly in the centre with the foot jewels; if so, you can put that down for the proper size; the next you want the strength. Before you take off old spring from balance, take hold of outer end with tweezers, and gauge the distance between balance and outer end of spring (while swinging), then put on new one, and gauge that, and if the distance be about equal, no doubt your watch will go about right. Before you pin up tight, if your spring is not flat, raise or lower it by the centre coil; when flat, pin up tight. If you will advertise your address, I will help you to put watch in thorough good order.—Nicholls.

[46417.] — **Instantaneous Photography.**— The unaided hand cannot expose a plate with sufficient rapidity to secure the impression of rapidly moving objects; but the hand can be used to liberate a spring that will expose for, say, 1-25,000th part of a second, and this is how the so-called instantaneous photographs are easily secured.—W. T. Bashford.

[46417.]—**Instantaneous Photography.**—In respect of the theoretical principle involved, your assumption is quite correct, and also in your illustration; but practically such a movement would not be detected unless the train were photographed broadside on. This, however, has not yet been accomplished. In the one or two examples of such which have been taken, the point of view chosen has been situate about 30° or 40° to the line of advance. An exposure measured by the fraction of a second could not be given by manipulating the opening and closing with the hands; but there are many mechanical arrangements for accomplishing this with almost inconceivable rapidity, and by which an exposure could be made of less than a 1,000th of a second. With a drop-shutter having a narrow slit, and working immediately in front of the sensitive surface, there is practically no limit to the shortness of time, especially if the gravity is assisted by springs. Jannsen claims to have made an exposure of about 1-3,000th of a second by these means. These short spaces of time are not assumed, there are instrumental means for measuring the intervals.—Baboon.

[46420.]—**Cupola.**—If "A Constant Subscriber" will advertise his address, I will give him all the necessary information, as it would take a deal of space to answer his query. I gave the sizes of a cupola to melt 5cwt. of iron two weeks ago.—Cast Iron.

[46423.]—**Gravity Clocks.**—To "Clerkenwell Clockmaker."—The barrel arbors of gravity or any other clocks do not require hardening. Some are even made of iron, but steel is much to be preferred.—A Clerkenwell Clockmaker.

[46425.]—**Gelatine Emulsion.**—But a very short time, unless you add an antiseptic. An ounce of a 10-grain alcoholic solution of thymol to each 10 ounces of finished emulsion will keep it good for a year at least.—Baboon.

[46425.]—**Gelatine Emulsion.**—I have kept unwashed gelatine emulsion containing a small quantity of acid (I think three grains to the ounce) quite good for nearly three years; after it had "set" in the bottle I poured over the top of the emulsion a small quantity of methylated spirit. This may have assisted in the preservation; I believe the washing would not affect the result. *Washing Emulsion.*—A very simple way of washing emulsion is to coat the plates with unwashed emulsion, and after allowing plenty of time to get thoroughly set, to place them in plate-boxes constructed to allow a stream of water to pass over the plates and out at the bottom of the box; after this washing for a couple of hours, or all night if preferred, near up to dry. This mode of washing has been peculiarly satisfactory in my hands.—W. T. Bashford.

[46425.]—**Gelatine Emulsion.**—Pour as much as you will want at a time whilst warm into separate bottles, and then you will not have to melt the emulsion more than once. Cover with alcohol when it has set, and it will keep well in a cool place. It is said to gain in sensitiveness by keeping in a moist state. To wash emulsion, get a piece of clean canvas, spread it out, and put emulsion in a heap in the middle. Then gather up the sides, and twist it so as to make the emulsion go in the form of a ball in the middle of canvas. Hold it under water in a large jar, and twist it till all the emulsion is forced out into long threads. Tie a piece of muslin over the jar, and invert it, and all the water will run out through the muslin. The washing is simply to fill the jar with fresh water through the strainer, shake it a bit, and allow to stand for five minutes, then drain off, and put more fresh water. I should do it about six times. When finished, it should be left to drain for two hours or so. I should think unwashed emulsion would keep as well as washed.—E. F. C.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[46427.]—**Electric Engine.**—I am anxious to construct a machine of this nature sufficiently powerful to drive, say, the overhead motion of my lathe in ornamental turning. The power required for this purpose is very little, say the eighth of a horse, or even less. Yet this power (though small) is required at times continuously for an hour or more. This, though by no means hard work with foot-motion, becomes tiresome and monotonous, and it has occurred to me that a motor actuated by an electrical current would be just what I require; being easily controlled, occupying little space, noiseless, and cleanly. There have appeared in the English Mechanic from time to time, numerous hints and disjointed instructions from different contributors; but so far as I have noticed, nothing sufficiently detailed or practical to induce an amateur to undertake the construction of a motor of this nature with the full assurance that when finished it would answer his expectations. Would Mr. Lancaster, or any other contributor well up in such matters, kindly give, through these columns, a drawing with fully-detailed practical instructions and dimensions, of an engine capable of giving out, say, a quarter horse-power, and possessing the following amongst other points of excellence?—Greatest power with smallest amount of battery waste; compactness; simplicity of construction; little liability to derangement; speed and power easily controllable; and economy in working; and at the same time describe the best-known form of continuous battery not liable to give off noxious gases. Now I believe that an article or a series of articles plainly and concisely written, giving every dimension, number, and mode of wrapping magnets, with every other particular, would be welcomed by many readers, and its construction undertaken by many amateurs requiring a small, continuous, and unvarying power. —Ivory.

[46428.]—**Pumping.**—Will any reader tell me how many gallons of water would a pumping engine throw at a stroke, running at the rate of six strokes per minute? The engine is 7ft. stroke, 12in. in diameter. Please put it in plain figures.—E. J. D. P. H.

[46429.]—**Skin Disease.**—Will Dr. Edmunds, or any reader of the English Mechanic who has been troubled with psoriasis, kindly inform me if it is possible to effect a really permanent cure? I have tried many remedies during the last five years (under the best medical advice at my disposal), both internal and external; but they have all failed to give more than temporary relief. I am inclined to believe that proper diet has a good deal to do with this trouble; because, during a voyage to India some years ago, the skin affection disappeared, owing possibly to the lack of milk; for on returning home and resuming the use of milk, the psoriasis came back again. As, however, a number of medical men assert that milk should be freely used, I am at a loss what to think regarding it, but shall be glad of any information.—Marine Engineer.

[46430.]—**Colours on Fabrics.**—What are the tests usually employed in trade to test the stability of a colour on a dyed or printed fabric? Maybe, Mr. Allen will oblige with the information.—Pro Bono Publico.

[46431.]—**Worsted and Woollen Yarns.**—What are the chief distinguishing characters between worsted and woollen yarns? Which of them dyes up the best and takes the most permanent colour?—Pro Bono Publico.

[46432.]—**Spiral Spring.**—Will any reader tell me how to make a spiral spring about No. 12 gauge steel wire, and how to temper? What kind of steel would you recommend for toughness and strength?—An Amateur Reader.

[46433.]—**Potato Disease.**—To Mr. Adams.—Will Mr. Adams, the writer of "Observations on the Potato Disease," last May, please say in what form the potash recommended should be applied?—M. E.

[46434.]—**Medical.**—To Dr. Edmunds.—Might I ask Dr. Edmunds if he would consider it indiscreet for a young man to marry a young woman aged 25 who has been troubled with pleurisy and sore throat? The querist, being left a widower very early in life, in consequence of his wife's decline, would fain ask if, in this case, the complaint might assume a serious form? The young woman's doctor has advised marriage.—Cautious.

[43435.]—**Magnetic-Bell Hammer.**—Might I ask Mr. Lancaster to inform me how to connect up a wheel revolving magnetic bell-hammer? I have taken it adrift, and forgot how to join up connections again.—Amateur.

[46436.]—**Chemical Balance.**—Can anyone recommend a good balance that will weigh from 50 grains to one milligramme, and not exceed £2 in price? It is for use in the study of agricultural chemistry. Any information will oblige—Agricola.

[46437.]—**Soda Lime.**—How is soda-lime prepared? What is its action on nitrogen? Give equation. Can the soda-lime from one combustion be used over again? —Agricola.

[46438.]—**Handel Organ, Crystal Palace.**—Can any of your readers inform me what alterations are being made in this instrument?—F. J. W.

[46439.]—**Legal**—Will Mr. Whetherfield, or some other legal gentleman, kindly answer the following?—A. left property in the hands of two trustees to be equally divided between B. and C. at the death of D.; C. died a few weeks before D. C. left all her share to E. unconditionally; but E. is the issue of C. by marriage with deceased sister's husband. There were two executors to A.'s will, but by some misunderstanding they were not together when the will was proved. The one that proved the will has handed over all the estate to B. I may say C. appointed the same executor to her will. He says that it is not necessary to prove C.'s will, because E is the issue of deceased sister's husband. Cannot E. claim her mother's share?—One Anxious to Know.

[46440.]—**Analysis of Soot.**—Perhaps some of our chemists will be able to give a few hints on the analysis of soot, and the ingredients usually estimated, with value per unit of each?—Agricola.

[46441.]—**Vacuum Brakes.**—Can any reader of the Mechanic tell me the name of the vacuum brake now in use on the Bristol end of the Midland Railway? How is the vacuum formed, maintained, and destroyed? Are there any books yet published, describing the various systems of continuous brakes?—M. B. W.

[46442.]—**Launch.**—To "Sunlight."—I shall be much obliged for a working sketch (with dimensions) of the most approved form of stern-tube bush, with wood bearings; and also of a thrust block and bearing for a screw-shaft 1¾in. dia. Does the advantage of having a propeller abaft the rudder outweigh the manifest disadvantage of the arrangement? Probably "Sunlight" has frequently had opportunities of judging.—L.

[46443.]—**French Wire Gauges.**—I should be obliged by the information what the measures in decimal inches are of the Paris and French wire-gauges?—E. T.

[46444.]—**Press for Moulding Blocks.**—I am making a composition which is to be made into blocks of the following dimensions; 2in. × 2in. × 3in. This composition is of such a consistency that if the hand be dry it may be handled without adhering to it. To make this material into blocks, I press it through a die and cut them off to the desired length. What I want is a machine which will make this material into blocks. Would a press such as is used by soapmakers answer my purpose, or could any reader give details of a machine suitable?—S. S. S. S.

[46445.]—**Gazogene.**—Will some fellow-reader tell me how to repair an ordinary domestic gazogene which leaks between the upper and lower bulbs?—W. H.

[46446.]—**Mr. Bennett's Battery.**—I have just set up one cell of this form, as described on p. 5, porous pot 6in. by 1½in.; tin can 4in. by 4in. Within five minutes of the solution being in, the bell started, and has been going for a couple of hours, and seems likely to keep on. It is ringing about the same as it does with two pint Leclanché's which have been going a twelvemonth. One thing I failed in—that was, getting the "potassium hydroxide," or "caustic soda," at anything like 2d. per pound. I went to a good wholesale druggists, and they told me "potassium hydroxide" was not "caustic soda," but "caustic potash"; so I had "caustic potash," and paid three shillings per pound for it. It is in round sticks, about ⅜in. by 6in. This makes the cell as dear as a "Leclanché," very nearly. What I want to know (and I don't expect I am the only one) is, how to get the alkali meant in the paper, whether it is potash or soda, at anything like a reasonable price?—W. W. H. G.

[46447.]—**Gauges for Lead Pipes.**—I have been in the trade of lead pipe-making for some years now, and we have only gauges made by ourselves. Would someone inform me is there a standard gauge, or is there any arithmetic rule that I could use for the purpose?—Thomas Price.

[46448.]—**Powder-Mixing Machine.**—I want to make a machine to thoroughly mix powders, about 56lb. at a time. Will some of my fellow-readers kindly inform me how?—H. T. J.

[46449.]—**Underground Siphon.**—To "Tubal Kain."—Oblige me with the following information. What should be the discharge of water in gallons per minute from a siphon-pipe 2in. diameter, and the pipes 300ft. long, and the fall of the same about 1 in 4, and the vertical height from the surface of the water, including the valve-piece to the top of the bend to the path of the incline, is about 3ft.? A formula on the above will greatly oblige.—Anxious to Know.

[46450.]—**Separating Fat from Mineral Oil.**—I have a quantity of fat mixed among mineral oil. Can anyone tell me how to separate the fat on a commercial and paying plan, or for what purpose could the mixture be sold as it is?—Chandler.

[46451.]—**Spring Blinds.**—I want to make a self-winding spring blind for outside of shop. Can any reader kindly oblige me with instructions how to make one about 10ft. wide—the kind of spring used, and the mode of fixing it, as well as the strength of spring required, according to size of blind, is what I want to know.—Engineer.

[46452.]—**To "Finem Respice."**—I am about to construct a brass camera on the principle of the one described in query 34379, Vol. XXVIII., p. 304; and should like to know if the size mentioned would be suitable for taking lake and mountain scenery: the lakes being about one mile across, and the mountains about 5,000 or 6,000ft. high? 2. If 1-32nd of an inch would be strong enough for a camera of 5in. dia to be made in two pieces, one to slide inside the other, rack and pinion being used to focus with? Can it be made light-tight on this principle? 3. Are Darlot lenses of 1in. dia. to be obtained ready fitted with rackwork and central stops? Can rack and pinion be purchased separate from the lens? —An Enthusiast.

[46453.]—**Mortgage.**—To Mr. Whetherfield.—M. took up a mortgage (£325) of C. for 15 years in 1861, to which 5 per cent. was to be paid yearly, but paid some time afterwards every quarter. C. sent M. six months' notice to call in mortgage on the 15th June, 1870. M. paid interest regularly up to 1869, and being pressed for money was not ready just at the time to pay the next three quarters of 1870. C. put M. in the County Court, and got judgment against her goods, and sold them on Dec. 23, 1870. On the following January (1871), C. put up property for sale, and said he sold it for £496. C. paid F. another £100 pounds that M. owed, but F.'s security was on a different property. C. was offered his own mortgage (£325), but refused to take the money before the time expired. C. will not answer any of M.'s letters; and he has had possession from 1871. M. went away on business before he sold the houses. Before M. came back, C. had got into the houses and turned a man out that was put in by M to keep possession. M. wants to know whether he can't recover property by paying the £325 and interest now? or if not, what is best to be done to bring the mortgagee to book? Can you tell me what it will cost? I am not able at present to pay a solicitor his charges till after I get my property.—George Mountjoy.

[46454.]—**Gas from Wood.**—How many feet of gas should I get from 112lb. of wood? Would the ash left in the retort be of any value?—California.

[46455.]—**Educational Prize Trust.**—Last year, one J. Bell, in London, offered prizes for the solutions of six numerical puzzles. Have the prizes been paid, and where have the solutions been published?—N.

[46456.]—**To Mr. J. Charles King, or any Wheelwright.**—I have a job to put a new hub to a very heavy timber gig wheel without taking it to pieces; every part is sound but the hub, which is broken out, being of bad timber; but the spokes are sound, and the felloes and strake tires are as good as new. To rip it to pieces and drive the spokes into the hub, and felloes on to the spokes, and then refix the strake tires red-hot, would make but a damaged job for many of the spokes and felloes, even if the wheels could be taken apart without breaking several of the felloes and spokes. How is the hub to be put into the wheel without disturbing any part of it?—Joskin.

[46457.]—**Battery.**—I have to thank Messrs. Tolman and Lancaster for their replies to my query about battery, and in answer to the latter gentleman, I may say that I require a battery-power equal to four quart Bunsen's cells, which can be kept constantly charged and ready for use at any time. It is to work an electric hammer which operates by means of a small electro-magnet, wound with No. 32 silk-covered wire. It is similar to the one used by dentists, and is worked for two hours at a time. Now I wish to know what is the most economical and best form of battery I can use?—Malleus.

[46458.]—**Fernery Pipes.**—In my fernery window the warming-pipes are of brass, and take a great amount of cleaning, as the drops of water tarnish them. They were not lacquered, because it was pointed out that this would turn black as soon as the hot water passed through them. Is there any kind of varnish or enamel that I can get to do them over with that will preserve their good appearance, both against the heat within and the splashings of water without? If anyone can tell me either how to make such, or what to get, and where to get it, I shall feel obliged.—Adiantum.

[46459.]—**Drilling Machines, &c.**—I have one of Mr. Cohen's little drilling machines, but can't make it any practical use to me. If I put stock in vice, I have to hold the article to be drilled in my hand. It will never do for me to hold it in my hand to drill pivot-holes in watchwork, for I can't hold it firm or steady enough for that. Would "Alfojoe," or others of the trade, kindly name the best sort of drilling-machine for an amateur clock and watch-jobber, who has not a mandrel or lathe; nothing but a small vice to hold the stock? I should like one that would drill from ⅛in. down to pivot-holes, either in brass or steel. I have thought about an American drill-brace with a gear-wheel. I thought by this I could put the article in vice, and hold the brace in my hand, and drill with greater speed and force than with the bow. Are those machines ever used by clock-jobbers? I am a self-taught jobber, and very anxious to learn the trade; if any will tell me how to proceed I shall be thankful. Can someone also tell me how to lessen a gold ring in diameter (without cutting it), and how to make gold paint for painting jewellery after it has been soldered?—A Learner.

[46460.]—**Tortoise-Shell.**—My tortoise has died, and as the shell is a nicely-marked one, I want to preserve it. Can any reader kindly tell me the best way to abstract the carcase? Would boiling affect the shell in any way?—W. G.

[46461.]—**Charcoal Furnace.**—Will a reader kindly inform me how to make a small charcoal furnace for heating retorts, crucibles, &c., and suitable for other general chemical operations?—Hugh Tunnadine.

[46462.]—**Measurement of Electric Current's Strength.**—Will someone kindly describe how I can make an instrument for measuring the strength of electric current in ohms or any convenient and well-known unit? I wish to find the power, as a generator, of a dynamo-machine I have constructed, but do not know how to set about it; oblige—Country Ploughboy.

[46463.]—**White-Lead.**—I intend to have a considerable quantity of painting (dwelling-houses) done, and wish to guard against adulterated white-lead being used, and shall feel thankful for a suggestion as to how I can do this. The best sample I can get from a shop is only 4·75 sp. gr.; and according to a rough test, appears to contain nearly 20 per cent. of baryta, and a large quantity of chalk.—Creta.

[46464.]—**Steel Rails.**—What percentage of their main lines have the principal railway companies laid with steel rails? Also, what are the weights per yard and lengths of the rails? What is the advantage of keying the rails on the inside, as on the Midland, instead of the outside? What companies adopt this plan?—McK.

[46465.]—**Midland Carriages.**—What is the length of the longest bogie carriage? What do the initials, "M. S. J. S.," on the carriages of the Midland Scotch trains, stand for?—McK.

[46466.]—**Staining.**—Will some chemical friend give a list of a few chemicals having such a marked affinity (like pyrogallic acid and ferric sulphate) as will be suitable for marbling or mottling, in imitation of tortoise-shell, horn and various fancy woods, giving the colour of the solutions and their precipitates?—W. W.

[46467.]—**Rheocord.**—Will any of your correspondents kindly inform me if they know any simple form of rheocord which will reduce voltaic currents to almost zero?—Physiologist.

[46468.]—**Brake for Omnicycle.**—I wish to have a band-brake to my omnicycle. I thought of having a grooved wheel with steel band secured to metal hub with three or four screws, and a handle to reach to my present rest-handle, and a click or dog to the handle to go into a notch secured to the side of the backbone; so that when the brake is full on it will remain fixed until, by a thumb-piece attached to handle, it can be relieved. Sketch will oblige—One in a Fix.

[46469.]—**Toning.**—Is it possible to tone platinotype prints to a purple or brown colour?—Lex.

[46470.]—**Diagrams of Oscillating Engines as on London River.**—Will some of "ours" say how these are taken, so far as the fair leads and gear are concerned? The pipe on which indicator is fixed stands up level with cylinder cover; how then is the string fixed to crank, and how conducted to same from the indicator? Clear particulars and drawing will oblige—Working Fitter and an Old Reader.

[46471.]—**Great Eastern and Great Northern Joint Line.**—Could some of your railway correspondents give me a little information about the above line, as I see that a portion from Spalding to Lincoln is now opened for traffic? What is the route the line takes? What works will be undertaken on the portion of the existing line between March and Huntingdon? When will the works be commenced in this locality? Who is the contractor for the construction of the line?—A Hunts. Man.

[46472.]—**Magneto-Electric Machine.**—Will some reader of the "E. M." kindly inform me how to make a magneto-electric machine, and how to regulate the current? Is the machine used in electro-deposition? I want, if possible, to use one for depositing gold and silver in the place of the Daniell cells I am at present using. A machine giving a current equal to two quart Daniell cells would be quite sufficient for my work.—A Young Jeweller.

[46473.]—**Pressure of Water.**—A lock-gate is 12ft. wide, and has a depth of 8ft. of water pressing against. What pressure does the lock-gate sustain? Also, if it be required to find the pressure against the lock-gate 2ft. from the bottom, how must I find it?—W. H. B., Bradford.

[46474.]—**Chime Clock.**—I have had the above to clean, verge escapement, good-going order; maker, Jonas Rant, London, no date. The owners wish to know the probable age. Can any of "ours" tell me what years the above maker carried on business in London? Also, what is the use of plate 1½in. dia. with figures on it from 1 to 12? This plate is between dial and hour-hand, and fitted a tube, the inner end at back of dial, had a pear-shaped boss which fitted loosely the tube or boss of hour wheel. There was nothing that I could see missing from the clock.—Hopeful.

[46475.]—**L. & N.W.R. Engines.**—Will any of our readers kindly give the number of Snipe, Skylark, Sheldon, St. Alban's, Telegraph, and Iron Duke? Also the dates of Atlas, Councillor, Elwy, Wyre, Simoom, Vizier, Vulture, Viscount, Lawrence, Medea, Lapwing, Arab, and Python?—Gem.

[46476.]—**Dull Window-Glass.**—I have some vineries and frames in close proximity to smoky chimneys of dwelling-houses of my neighbours; and in consequence they are always dull and obstruct the light, being covered with fine soot, which seems to penetrate into the very substance of the glass. I have tried scrubbing with soap, and also washing with hydrochloric acid; but all to no purpose, and they appear to get duller every year. Can any kind reader tell me how to remedy this?—Caxton.

[46477.]—**G.W. Engines.**—Wanted the dates and size of cylinders of the following engines?—1581, 1513, 1220, 852, 826, 780, 619, 487.—C. H.

[46478.]—**L. & N.W.R.**—Will some reader kindly favour me with a sketch and detailed dimensions of the L. & N.W.R. tank engines (outside cylinders, four-coupled, dome close to funnel) which run on the North London Railway from Broad-street?—E. E. R. Tratman.

[46479.]—**Steam Carriages.**—Can any reader give me a sketch of the following steam-carriages, mentioned in Mr. Clarke's "Locomotive Engines," with particulars?—1. "Enfield," Eastern Counties Railway, when Mr. Samuel was engineer of that line. 2. "Express," same line; but, I think, of more recent date. 3. "Fairfield," which used to work the Tiverton branch (broad gauge) of the G.W.R. I believe all three were constructed by Adams and Co.—E. E. R. Tratman.

[46480.]—**Landlord and Tenant.**—To Mr. F. N. Wetherfield.—Tenant took furnished rooms at per week. Having occupied them, and was given latch-key, afterwards arranged for an employé to occupy them. He also was supplied with key. The rentbook was kept and paid in the name of first tenant, who was considered responsible. The employé was called away suddenly, and never gave notice to give up rooms, the bill being forwarded, the first or responsible tenant still holding his key, and neither having given notice. Can I recover rent and price of key? And does the fact of holding key constitute tenancy?—Householder.

[46481.]—**Boiler-Pump.**—To "Sunlight" and Others.—I have a boiler-pump worked by an eccentric on flywheel shaft. I want to know how much water per stroke it sends into the boiler. My idea is to multiply the length of the stroke by the diameter of ram.—Slocum Podger.

[46482.]—**Gregorian or Cassegrain.**—To "A. N. H."—I am sorry I did not mention the distance between the mirrors in my last. It must be about 22in. Will you kindly suggest curves? If you have had experience of Cassegrain's telescope, perhaps you will let me know what you think of it?—G. L. E.

[46483.]—**Diamond Work.**—Could any of your readers inform me what alloy is used for diamond spray-work, or if it is just the pure silver? as I find our work to tarnish quicker than English.—Jeweller.

[46484.]—**Lathe.**—Will some of our lathe correspondents kindly advise?—I have a 3½in. back-geared lathe, in which the backgear slides endwise in and out of gear, and the pulley is fastened to front gear-wheel by a small bolt and nut sliding in a slot in front of wheel. I want to put a division-plate on front of cogwheel, but must have a different way of clamping pulley to mandrel first. I thought of doing it a way I have seen some, with a nut on mandrel at the back of the pinion on pulley, and this is screwed up tightly when working without gear and holds by friction between pulley and front gear-wheels. But the space between mandrel and back gear-wheel is only a little over 3-16in., and that is not enough for a proper nut. Would it do if I had a cylindrical nut, and screwed it by a sort of hook-wrench put into holes in its surface? Would a nut only 3-16in. thick be strong enough? If this way is not advisable, could someone tell me how to manage it without using front of mandrel gear-wheel?—E. F. C.

[46485.]—**Pedal Organ, &c.**—Will one of our correspondents in such matters advise me whether to build an 8ft. or 16ft. tone pedal Lieblich bourdon to a one-manual organ containing Lieblich Gedact, 8ft.; Gamba, 8ft.; Dulciana Principal, 4ft.; and Fifteenth, 2ft.? Also, give address of a firm who supply the strained and unstrained white leather for bellows, pallets, &c.? Organ-builders are so exorbitant in their charges for these things.—Sly Dog.

[46486.]—**Baking.**—I wish to commence a bakery capable of turning out 70,000lb. of bread per week. What is the most improved method of kneading? Which is the best style of oven, and how heated, and where can they be seen at work? Any other information will be welcome.—H. Washington.

[46487.]—**Chemical.**—Would any chemist kindly furnish a simple and easily-applied test, whereby salt-water may be distinguished from fresh when absorbed in small quantities by cotton, jute, or other fibres, either in the raw or manufactured state?—L'pool, N.

[46488.]—**Legal.**—To Mr. Wetherfield.—A. owns a foundry at the back of B.'s house. The chimney connected with the boiler was, until recently, carried to a distance of about 50ft. from B.'s house, and then to a height of about 30ft.; but a new boiler has been put up, and the chimney carried straight up not more than 15ft. from the ground. It is now close to B.'s garden-wall, and about 15ft. from his house, and the volumes of smoke are a continual nuisance. Is this allowable; and if not, what remedy is there?—E. J. Babbage.

[46489.]—**Bicycle Making.**—I shall feel obliged to any of our readers who could inform me whether, in fitting neck and back-fork in backbone and front forks (hollow) to head, they have to be drilled and pins or rivets put through in addition to brazing, or will brazing alone suffice to hold them? I may mention that it is a 48in. all-bright machine I intend making for my own use. Any hints on the fitting, &c., of machine together will be thankfully received by—An Amateur.

[46490.]—**G.P. Joints.**—Will one of your readers kindly inform me how the joints are now made in the underground (street) telegraph wires? The Chatterton's compound, which was formerly used at each stage, has, I believe, been discontinued; and nothing but sheet percha used. Perhaps one of your readers would kindly give the details, how to make a joint to test well and look well?—Inspector.

[46491.]—**Telescope.**—To Mr. Lancaster.—I have a 48in. telescope, 1½in. aperture, and, strange to say, when I look at an object a sort of cloud covers the eyepiece. This is removed by removing the eye about an inch from eyepiece of instrument. I should like to know what is wrong?—Object.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, March 22, and unacknowledged elsewhere:—

R. Healy.—John Wilks.—R. O'Hara.—J. Bateman.—Chance Bros. and Co.—R. Vion.—Rev. W. L. Pendered.—G. W. Weeks.—J. Noble.—Rev. J. Rawlins.—F. Nunns.—Collodion.—Starlight.—Poor Peter.—Total Heat.—T. Neilson.—Platform.—Kappa.—Meteor.—N. S. Godfrey.—R. P.—Amateur Polisher.—J. H. B.—Vega C.—Gymnastic.—Jumbo.—Fellow Workman.—W. G. S.—Fond of Wood Turning.—G. Tolman.—Conrad.—F. W. G.—W. Hosken.—Clyde.

A NEW VOLUME.

No. 885 was the first of Volume XXXV. Reader willing to oblige us by recommending "ours" to new subscribers should do so now, when a new volume is commencing. The index to Vol. XXXIV. is published in this number and cases and bound volumes will be on sale shortly. Readers desirous of making up their sets for binding the last volume are recommended to do so at once, as the back numbers soon run out of print.

Enquirer. (You can obtain a copy at Somerset House or your local private registry. The cost is not heavy, but according to length.)—U. S. A. (We cannot insert queries asking for information about persons. 2. The climate of the district named is the most enjoyable in England, except in the extreme south-west, where a great deal of rain falls. Penzance or Falmouth ought to suit you, and if you find them too relaxing you can easily shift your quarters to the northern coast, where the fresh breezes from the Atlantic sweep "all down the thundering shores of Bude and Bos" at a rate that ought to satisfy the most ardent lovers of the boisterous.)—E. Berliner. (Received with thanks. Will gladly accept and report.)—S. Croft and Sons. (We do not know the address. You had better ask "Tubal Kain" for it through the "Address" column.)—Would-be Watch Jobber. (We do not see that you can do anything else but follow Mr. Beaumont's example as detailed on p. 628. You are evidently hardly prepared to start in business for yourself yet.)—Man of Kent. (We are of the same opinion as your medical man, and even if you still experience no ill effects, should advise you to be very careful.)—Oxodus. (If your hip joint is really dislocated, you had better see a surgeon, and not waste valuable time in quacking yourself with galvanic bands for rheumatism and liver complaints, or listening to old women's tales about "want of oil in the sockets.")—Clean Water. (You can do nothing with the filter but get rid of it, and get another with a movable top, so that you can yourself remove and clean the charcoal block at least once a month.)—E. Carter. (Received, but could not spare the necessary space. We have already devoted some room to the association, and wish it all success, but are very crowded just now.)—

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, MARCH 31, 1882.

THE GONIOSTAT.

By J. H. EVANS.

THIS instrument is one of the most useful, and is, consequently, a necessary adjunct to any amateur mechanic's workshop. In the first place, it is as well to draw attention to the fact that a great many tools are often entirely spoiled from being badly ground; the angles are rendered anything but what they originally were, and, therefore, a reproduction of any work previously done by a cutter that has been ground by hand is quite impossible, and it is to aid those in want of the knowledge of such instruments as the engraving represents that I endeavour to give all the details necessary for making such a tool. There were, at an earlier period, several different plans devised for effecting the same purpose, but I think the present one is the best in every way. It was a rule not long ago to fit the instrument into a box, having three trays to draw out, each one having a different plate let in —viz., one of oil-stone, one iron, and one brass. But I have arranged it on a different principle; that is, to have a mahogany block 9in. by 12in., and all the three sharpening plates on the same surface; the Goniostat is fitted in the centre of the block, and a mahogany cover fits over the whole lot, so that it is simply to remove the cover, and when setting the tools they can be passed from one to another of the plates in much less time and with greater facility than when the plates have been taken from different places. When getting up a cutter to perfection it should be finished upon the iron plate with a little crocus. We find that a keener cutting edge is thus obtained, and I would here advise all who essay to try ornamental turning, never to be afraid of devoting time to sharpen the tools before beginning to cut.

To make such an instrument will require excellent work, and although there is not much to look at in it, it is by no means an easy thing to do. Fig. 1 represents a front view of the instrument, and shows distinctly how the different angles are obtained. It will be seen that the arc is equally divided on each side of the centre line, so that double angle tools may be got up to the greatest perfection. Fig. 2 shows a side-view, whereby the divisions on the steel arc are seen, also the manner of putting together the knuckle joint, and the two steel pins upon which the instrument is worked. Taking the side view, it will be seen that the steel piece Fig. 12 is fitted to the metal, and curved to fit over the top of the steel arc, so that when the screw C is tightened, the curved piece will clamp down upon the arc, and hold it tightly to the division at which it is set. The engravings are made to exactly the half-size of the original, so that little or no difficulty will be experienced in making patterns, and to facilitate operations I will, at any time, allow castings from my patterns, and so save any trouble at all in that respect. Having, then, the castings and forgings all ready, first see that all the rough edges are taken off, and as a beginning take the large plate, Fig. 3, and get the front up to a surface; then place it upon a wood chuck that has been previously surfaced, set it so that as much of the back of the plate as possible can be turned between the projections where the tool-box, Fig. 5, fits, and that in which the arc works. In making them we generally have three or four placed on a large chuck, and turn them all at the same time. When turning one, however, the same process must be gone through, and to hold it to the chuck, good strong cement is the best, as it does away with clamps, which are sometimes in the way. I had better give the proportions for such cement as we use, and find answer in every way: It is simply made of resin and beeswax, two of the former to one of the latter, made hot in a small ladle and placed round the edges of the work with a spoon. When the work is turned a slight blow with a hammer will loosen it all, and the cement can be used over and over again. This, I may mention, is a most serviceable item in a workshop, and is used for many other purposes. Having turned the back, the parts not turned should be filed off true to the turning, and if well done, and the plate has been flat upon the chuck, it should be the same thickness all over. This being the case, the outer edges may be made to the proper shape. We may now proceed to bore the hole A, Fig. 3, in which the pin of the tool-box A, Figs. 5 and 6, is to be fitted; although the drawings are made half-size for the convenience of the paper, they will give the dimensions. I will give, however, the exact sizes for the various fittings. This hole then, A, Fig. 3, is ⅜ of an inch in diameter, and countersunk at the back, with a pin countersunk ⅝in. diameter, and 3-16in. deep. The screw may be made with the thread that is the most readily obtained, and, as these appear to be the Whitworth threads, as a rule, the 3-16 of that make will do perfectly well. Before proceeding with the steel parts, the action had better be got to work; therefore, Fig. 4 must form the next piece to do. The thickness of the front plate is ¼in., so that Fig. 4 should be the same. The top having been filed up flat, let it be placed on a chuck and turned in the same way as Fig. 3. When done, it can also be shaped up to what is required. It will be seen in Fig. 4 that the points of the screws project through about an eighth of an inch. The heads of these screws are ⅜in. diam., and the screw may be the ¼-Whitworth. I will take it that these shall be considered the threads throughout, provided the finer threads, which have been discussed, are not in the possession of the person about to make such a tool as that now under our notice. The screws in their place, the joint will be the next thing, and to file it up to a perfect fitting is not an easy task. I will endeavour to give the best idea I can of doing it to perfection. Having the two screws in their place, we will leave them for a time, and cut out the place where the curved parts in Fig. 4 are to work into Fig. 3. In order to get these out well, a long countersink, with a pin on it the same size as that on the points of the screws,

FIG. 1

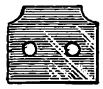

FIG. 6

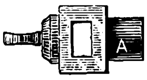

FIG. 13

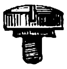

must be made, and it must be made sufficiently long to allow the chuck in which it is fixed to revolve without interfering with the sides of Fig. 3. The diameter of the joint to be cut is exactly $\frac{3}{8}$in., so that that must be the size of the countersink, and it must only be made to cut on the end. A small hole the size of the pin on end of screw must now be drilled in the metal in a line with the back face of Fig. 3, and side of it cut away with the countersink till it reaches the body of the metal, where it fits between the space seen in Fig. 4. Having cut out the place for the joint, to fit the other portion will form the next part, and I will, as I say, give a hint as to the best means to adopt. I have said that the screws are $\frac{3}{8}$in. dia. in the head, which is the exact size of the countersink, and we have found the surest way of making a good joint is to make a pair of screws with the heads the exact size of the countersink used to cut the recess and harden the heads; this will be a guide to file the joint to, and the screws being hardened will prevent too much being taken off where it should not be. Care must, of course, be exercised, or the files will soon be of little use; but a good viceman has no need to damage the file because the guide is hardened. It will be observed that where the instrument is jointed it opens to a right angle, so that more than half the circumference must work freely. Having the body of the work jointed up, the steel arc, Fig. 7 will be the next part to proceed with. The radius of it must be described from the centre of the knuckle-joint, and the best way to get the arc to its proper curve will be to take the centres and strike out the curve on a small plate with a square edge, the latter being for the purpose of placing the base of the steel arc, Fig. 11, against to test the accuracy of the work as it proceeds; if the dimensions are carried out according to the drawings, the curve will be easily obtained, and it will save a deal of trouble; it is $\frac{1}{8}$in. wide; the two holes seen in Fig. 11 are countersunk with a cone countersink, but this is not a matter of much importance. The shape of the heads may be different if desired.

The two holes seen in Fig. 4 are those into which the screws fit to hold the arc to the metal; the mortise hole in the front plate, Fig. 3, is that which the steel arc passes through, and must be very carefully set out, as it should touch the steel at any part during its movement—that is, when set by any angle denoted by the divisions on the arc. When this has been so far finished that it works well, we may proceed to fit the tool-box, Fig. 5. This is made of steel, and a forging will be necessary, on account of the various projections in it. The steel being properly softened, the pin A must be turned to fit into the hole A, Fig. 3. There are two different ways of holding this piece while being fitted: either to fix the square part in a jaw chuck, or to centre it and turn it between the centres. It the latter way, it must be made the length required, which will, of course, be the depth of the hole into which it is to be fitted, and then drilled and tapped. Whichever way it is to be done, the bottom face must be turned quite true to the pin, so that it will move round in its place without injury to the face of the metal. I should always recommend turning such a fitting between the centres, especially where, as in the present case, the reverse side has to be turned. When the pin has been properly fitted, it must be reversed between the centre and the boss, turned with a hollow true to it. This side is also tapped 3-16in., and has a thumb-screw fitted to it to fix the tool in its place; towards the end of the thin piece nearest the division, a piece of metal is fixed so that the end of the tool will pass through. This is to steady it, and make it more rigid when being set; also to insure its being square to the instrument. The best way to fit the metal piece in is to make two dovetail slots, and fit the metal to them, and slightly rivet it over at the bottom. It will be seen by the engraving, Fig. 1, that the end of the tool-box projects just beyond the radial slot: and on the extreme end it is filed to an angle, in the centre of which a fine line is made to read off the division on the metal-plate. The radial slot B, Fig. 3, may now be got out, and there are two different ways of accomplishing it. One way, and a simple one, is to line it out carefully from the centre of the hole A, and then drill a series of round holes close together, and with a round file break them one into the other. This done, it must be made quite true with narrow pillar files, and a small crossing-file for the concave part. This may appear an old-fashioned way in these days of drill spindles, overhead motions, &c., &c. The best way, however, is to bring into use the last-mentioned tools; and to do this, the plate, Fig. 3, should be placed upon a true surface-chuck—I think a wooden one the best for many reasons. It must be chucked quite true to the hole A, and to insure this a boxwood pin fixed in the centre will suffice. In making quantities we have, of course, proper standard chucks; but all that is really required is that the slot should be true to the hole. When it has been fitted as described, it is held down flat on the chuck by a clamp at each of the two corners. This done, a drill-spindle is placed in the sliderest, having in it a small rose-end cutter, and this, driven at a high speed, will soon cut out the slot both clean and true. If a segment apparatus be on the lathe, by all means use it, for the distance of the cut each side; if not, the length being lined out, no difficulty will be experienced working the lathe-head backward and forward by hand. To cut out such a slot in the latter way is, of course, the most practical; but still, in the absence of the tools, it can, and must, be done with a file. When this part is finished so far, and the tool-box fitted, it must be put in its place, and by making a line on the steel the width of the slot, the position for the binding-screw, Fig. 8, may be determined. This hole is tapped, or rather can be so, with the 3-16, and the plain part made to pass freely through; the screw should have a thin steel washer under the head, as it will hold the tool-box down better. It is not absolutely necessary, but it is better to have it. The diameter of the head of this screw should be half an inch, or as large as possible, provided it will pass by the under part of the steel arc.

We now come towards the finishing of the instrument. The two pins, Fig. 9, which screw into the two holes, A, Fig. 4: these must be precisely the same length, which is $\frac{3}{4}$ from the shoulder, and screwed tightly up to the collar, which, in order to give a better hold, should be $\frac{3}{8}$in. diameter. These having been fitted, we may look upon the instrument as ready for dividing, and the starting-points must be taken when the two pins, Fig. 9, are in their places. If these were to be shortened or lengthened afterwards, the divisions would be incorrect. As to the actual finishing-off of such a tool, this is entirely in the hands of the person who is making it. It will, of course, work just as well without being highly-polished; but if it is desirable to do so, the same directions as I have given for other work will apply in this case.

THE ECONOMY OF ELECTRICAL RAILWAYS.

On Friday last Prof. Ayrton, lecturing at the Royal Institution, made out a good case for an actual trial of an electrical railway on a working scale,—such a scale as would be necessary for the conveyance of passengers and goods over a light road of the ordinary gauge. The standard gauge must be adhered to for two reasons—because the comparison will then be direct, and because there is no likelihood of its being changed, even if the motive-power employed on railways were revolutionised. The question whether locomotives shall be employed to do the hauling, or whether current shall be supplied to electric-motors from dynamos driven by stationary steam-engines, is purely one of cost, and from that point alone can we expect directors and engineers to examine the scheme propounded by Prof. Ayrton on behalf of himself and Prof. Perry. If, in addition to economy of making and running expenses, it can be shown that railways worked by electricity are safer than the present system, there is much reason to wish that a trial on a large scale should be made as soon as possible, though it is scarcely to be expected that the experiment will be made on the Underground line. In examining the question by comparing the relative advantages and disadvantages of the rival systems — for the electrical is so far perfected that it is a system—it may be advisable to point out the weak points of the ordinary system in which trains are hauled by steam-propelled locomotives; gas-engines, compressed-air motors, &c., being practically out of court. The first disadvantage is clearly that which was pointed out years ago, when Stephenson fought the battle of the locomotive, viz., it has to pull its own weight in addition to that of the train. On the average we may say that it is equivalent to six carriages full of passengers, and for obvious reasons a large proportion of the weight is carried on a few points, so that not only must the road be made strong to carry the weight, it must be made very strong, and be carefully looked after to prevent and remedy the damage done by heavy loads passing over it at high speeds. An ordinary third-class coach, full of passengers, weighs less than 10 tons, while an engine weighs, say 40 tons, two-thirds of which rest upon the rails in as short, or probably a shorter, space than that occupied by the wheel-base of the passenger coach, so that while the coach presses the rails at four points with $2\frac{1}{2}$ tons at each, the four coupled driving-wheels press on them at each point with a weight of 7 tons. It is clear that, besides the disruptive effect produced by the passage of such a load at high speed, there is great wear and tear of rails and tires. In Stephenson's time the alternative was a stationary engine, to draw the train by means of ropes and chains, a system which that far-seeing engineer said would never do for the railways of the future, and though quite aware of the drawbacks to the use of the locomotive, he also did not fail to notice the enormous waste of power in hauling chains and ropes over pulleys and drums. But if we can dispense with the heavy non-paying weight of the locomotive—which is a costly machine at first and expensive on repairs—it follows that railways will cost much less to build than they do now, and will be maintained at far less annual expense. Then, a locomotive weighing as much as six carriages, and an average train being taken as ten coaches, it is clear that 50 per cent. of the total power is expended in propelling the engine itself, and as that means 50 per cent. of the coal burned, there is a large margin of economy on that item alone, if other things are equal. It is well known that a horse-power can be produced in a compound condensing engine at a smaller expenditure of coal than is possible in a locomotive, so that we may fairly say 70 per cent. of the fuel necessary to propel a train can be saved by dispensing with the locomotive and making each carriage self-propelling. In the electric transmission of power there is waste from mechanical friction and from electric friction; the latter can be avoided or reduced to a minimum by making the load on the motor so small that it will run nearly as fast as the generator which converts the mechanical energy of the steam-engine into electric energy. Experiments have been made which show that the efficiency of an electric-motor is 70 per cent. of the work done by the steam-engine; but, if we put the loss between the engine and the dynamo at 20 per cent., and that between the dynamo and the motor at 20 per cent., the total is 40 per cent., against which we have a set-off of 70 per cent., leaving a balance of 30 per cent. of fuel saved by the use of electricity. Another series of experiments have proved that a horse-power can be obtained for every 50lb. dead-weight of electro-motor, and we must remember that these machines are still in their infancy. Still, a horse-power for every 50lb. dead-weight is a long way better than can be done with a steam-engine, and is more than twice the power obtainable from a similar weight in a locomotive. The great advantage of the electric motive-power under this branch of the subject is, that the power will be distributed: each coach will be fitted with motors capable of propelling it, and there will be no necessity for using a machine capable of hauling a dozen carriages when it is required to take only three or four. We have no intention of entering into the theoretical aspects of the question: they will be found treated by Dr. Werner Siemens on p. 202 of our last volume; but having seen that the economy of the electric system is clearly superior to that of the steam locomotive, it remains to be discovered how best to utilise electricity. The chief difficulty is the conveyance of the current to the motors without undue loss through heating of the conductors, and without leakage—a very serious loss where long conductors are inefficiently insulated. The simplest method is obviously to use the two rails, one as the lead, the other as the return, the connection being made through the motor by means of the wheels on opposite sides. These necessarily must be insulated from one another, or the current would pass through the axle instead of the motor. That is the system adopted in the Berlin railway, but later modifications use both rails as returns, and have a special rail or cable for conveying the current. Both these methods have disadvantages, the chief of which is the great loss by leakage, a loss which Profs. Ayrton and Perry believe they can minimise. In the paper by Dr. Werner Siemens (see p. 202, Vol. XXXIV.), that distinguished pioneer in electrical engineering expressed the opinion that the electromote would never supplant the steam-locomotive, mainly because the latter possessed "freedom of motion," or is self-contained; but he thought that electrical railways might with advantage be erected in crowded districts, and be used especially in tunnels and for underground systems. Profs. Ayrton and Perry have gone a step beyond: they evidently think that the days of the locomotive are numbered, although a tolerably long life may still be in store for our old servant. They propose to lay a well-insulated cable alongside the line, and take the current through the motors by means of a rail on which the train will rub, and which will be divided into sections, fairly well insulated from one another and from the ground. By means of connections automatically worked by the train, the current would be supplied only to that section on which it was for the time being required, and consequently the loss from leakage would be reduced to a minimum; in fact, Profs. Ayrton and Perry "venture to think" they have reduced the leakage on the longest railway to less than what it is on the shortest by any of the systems hitherto suggested or tried. Several methods of making connections between the sections and the cable have been devised, but one in which contact-boxes are used at every 50ft. or so, would involve a considerable outlay of capital, and is, we consider, out of the question. In the simpler form, the rubbed rail is divided into sections as long as the method of insulation will allow, and a train passing out of one section takes off current from that section and puts it into the section just entered. Thus there must of necessity be a clear space of a section between two following trains, for a train having left section A, and entered upon B, the section behind is blocked, and any train entering it is automatically brought to a standstill, for the reason that it is not only deprived of motive power, but is actually braked by the electro-motor becoming a generator short circuited on itself. With such a system as this it is evident that signals could be dispensed with, while by suitable arrangements the train could be made to automatically record its progress along the line to all the stations. As to the motive power, stationary steam-engines would be erected at suitable spots, where space could be obtained cheaply; but there would be dynamo-machines to generate the current and electro-motors on the axles of the vehicles. What these would cost and how long they would run without repairs we have no data on which to found even an estimate, but there does not seem any reason why they should be more expensive than locomotives, and they certainly would not cost so much in repairs. There is, then, the capital outlay for the cable, the rubbed rail, and the contact-making connections, which would scarcely be covered by the saving in signalling wires, especially where there were many junctions and both signals and points absolutely necessary. These details of expenditure are not at present forthcoming, but it is probable that the large saving in forming the roadway and building bridges would more than cover the outlay incidental to the electrical system. There is no present probability of any of the main lines altering their arrangements in order to introduce electro-motors, but there is plenty of room for making light railways and putting the new system through a thorough trial.

EXHIBITION OF BICYCLES AND TRICYCLES AT BIRMINGHAM.

AN exhibition, promoted by the Speedwell Bicycle Club, was opened on the 22nd inst., at Bingley Hall, Birmingham, and as the first provincial exhibition of its class it proved a decided success, both as regards its exhibitors and its visitors. Bingley Hall is well adapted for exhibition purposes, and possesses, besides ample floor space, an extensive gallery, which was used for showing the capabilities of the various machines. The entries numbered about 300, and most of the first-class makers were represented. Messrs. Singer and Co. exhibited about a dozen machines, all of which maintained the reputation of this firm for design and finish. The "'Xtraordinary," recently noticed and its merits discussed in our columns, attracted much attention. Messrs. Baylis and Thomas, whose novelties for the season were mentioned some short time since, exhibited several specimens of their manufactures, including a "Stanley Excelsior Hollow-fork" semi-racing bicycle, a splendid machine, which was much admired. The Machinists' Company showed an assortment of machines, as did also the Caroche Company, including a Juvenile Tricycle and Sociable. Amongst the novelties exhibited must be mentioned the "Four-in-Hand," a most imposing-looking machine, manufactured by the Centaur Company. It is constructed to carry four riders, two ladies in front on seats, and two gentlemen behind on saddles, all facing front and pedalling forward. It is very little larger or heavier than an ordinary Sociable, and consequently the extra pedalling power makes it unusually easy of propulsion. It is finished and fitted in a very superior manner, and was one of the best machines in the exhibition. The same firm also exhibited their "Convertible," which can be used as a double or single machine (by an extra wheel being supplied), and can be converted in about three and a half minutes. Mr. Burdess showed a machine, the novelty of which consisted in a backward action of the pedals instead of the ordinary forward motion. Amongst the Howe Machine Company's exhibits was the new tricycle invented by Mr. S. Warwick, whose patent they use. It presents several novel features, one of which is that by a new gearing, worked by a simple movement of the handle, speed on a level road can be instantly changed for power when hills have to be climbed; the same action also works an arrangement which stops the pedals, so that in descending a hill the feet remain stationary while the machine is in motion. There was also exhibited by Mr. Eade, a special hill climber, the "Monarch," which it is claimed will easily ascend the steepest hills. Mr. Eade was not content with saying what his machine would do, but had fixed a steep incline about 1 in 7, and some 20ft. long, across which was fixed, at the steepest point, a piece of wood 2½in. square. The "Monarch" was easily ridden up and down this incline, and passed over the bar in the easiest fashion. It appeared thoroughly under control on any part of the gradient, and attracted much attention. The Small Arms Company (Limited), and the National Arms and Ammunition Company (Limited), both exhibited several machines, which bear the stamp of the excellent workmanship that might be looked for from these firms. Mr. G. Townend, who makes a speciality of juvenile tricycles, exhibited several machines, and they appeared, by the juveniles who were riding them about, to be very easy of propulsion, and quite safe. The "Hopwood" pedomotive-carriage, is an entirely new machine, which the inventor states is neither a bicycle nor a tricycle. It is constructed to carry two persons as passengers, and is intended to be worked by a coachman or "outrider." We were not able to see this machine completed, as it was late in arrival, but mention it as a novelty which we shall notice again.

The Manchester Tricycle Company exhibited a "Favourite" machine worked by the hands only, which they say is specially designed for those whose legs are weak or useless; to such this machine may be a boon, but the seat appears to be uncomfortably low. Messrs. Palmer and Co. exhibited a tricycle which has their patent centrifugal balance movement, very ingeniously constructed and well worth the attention it received. Mr. Lucas, of "King of the Road" renown, as applied to lamps, was there with an excellent display of his manufactures, and showed his latest improvements, which are an adjustable wind-up burner for regulating the light without opening the lamp, and a contrivance to prevent smoking. Mr. W. Bown had a very large display of bicycle fittings, &c., all of which were of excellent finish and workmanship. Mr. Bown is, however, more celebrated for his "Æolus" bearing which has been, from its first introduction, most extensively used by nearly all the prominent makers, The front wheel bearing has this season been so far improved that the outer case and cap are made of solid stamped steel, the internal curved surfaces being left dead, hard, and highly polished. The adjustment is also improved, so that the lock bracket cannot become detached from the serrated edge of the cap. Most of the machines exhibited were fitted with the "Æolus" bearings, which are highly esteemed by both makers and riders.

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(Continued from page 25.)

New Holes.—(*Continued.*)

DRILL the hole the rest of the way through; now rivet the bush firm, and broach the hole, so that the wheel will run easily; countersink it on the outside, and polish off level on the inside.

This method answers for third wheel, contrate, and small holes in general. The centre and fusee holes seldom require repairing. The centre hole is filled up and drilled in the centre of the countersink. The position of the fusee-hole is first got same as small holes, then filled up as follows:—Broach hole larger; then take a square file, and file notches round the inside of the hole—this will keep your bush from slipping; chamfer it a little on both sides, fill up, and make your hole. Brass is one of the most treacherous metals we have to deal with. You may think you are drilling it straight, but when you have done you will find your mistake; so you had better, when drilling large holes, to drill a small one first, and then broach it to the required size.

In fitting screws to regulator, cock-plate, or barrel-bridge, to make the hole for the screw, you proceed similar to fusee-hole, only you don't want the position. After you have filled the hole up (we will suppose you are fitting a new screw, hole, &c., to regulator, or time-plate as it is sometimes called), you put regulator in its place; then take needle, and make mark round the inside of the hole in the regulator: this will give you the position of the hole required.

The following is an easy way to put a pinion to contrate-wheel:—Take your pinion, in rough, and fit on carriage (19 and 20), as shown at Fig. 25; now fit a small drill-head, or rose, over the end of the pinion, as shown Fig. 25 (the dotted lines), leaving just length enough for your pivot. Now place it in the turns, and with a good pivoting-file file up pivot as follows:—Fig. 26 shows: C is a piece of brass, or steel wire, cut half-way through with a little slot B, made with a three-square file for the pivot to rest in while it is being filed; D is the pinion, E the rose, the dotted line A is the file. While you push the file from you, you draw the bow towards you in a see-saw fashion.

19

20

21

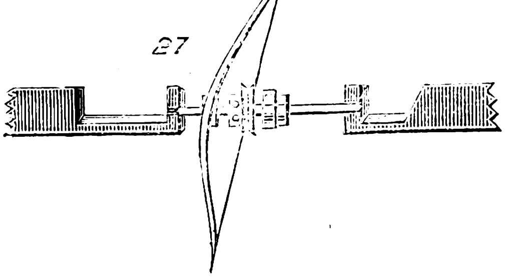
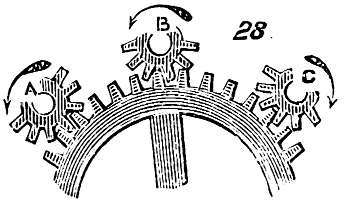
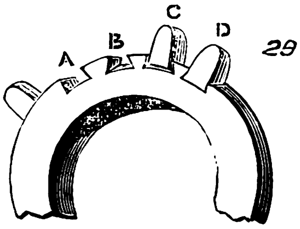
27



28



29



You must keep watching your pivot, or else you will soon find it disappear. When you have got it small enough, you must polish it. If you have not a polisher you can make one. Take an old, small file, grind it smooth, and polish it with oil-stone, or anything that will give it a smooth face; put some fine emery on a piece of wood, the same as on a knife-board. Now lay the tip of your file on the board, and slide it on to the board, not straight, but from right to left, three or four times. Now remove all traces of emery from the polisher, and it is ready for use. The other pivot is done in the same way, only you must be careful not to break off the pivot you have just made. When you have finished both pivots, you must turn up for the wheel. You must place your pinion in the turns in such a way that you may not break the pivots off while you are turning for the wheel. I think that Fig. 27 will sufficiently explain what I want you to understand about the protection of the pivots. You first drill a hole through, larger than the pivot, then you chamfer this hole about half-way through: this chamfer must be large enough, so that the shoulder of your pinion will enter and take its bearing, letting the pivot run free. Now turn up for wheel, same as Fig. 21. A should be a little chamfered, B more so, to allow of its being turned over for riveting. You must keep offering your wheel, so that you do not get it too small. When it enters about half-way, you can drive it the rest; then with a pointed tool you can turn over the flange B. It will not require any more riveting. I forgot to mention that you must measure from shoulder by the old pinion, as they must both be the same length. Now place your wheel in a pair of simple callipers with touch (Fig. 23), when, by turning the wheel slowly round, you will soon see if the wheel runs true. If not, put it between the plates with the escape-wheel, and see if any part of the contrate-wheel runs the right depth (see Fig. 28).

A is right, B is too deep, C is too flat. In A you will see that there is only one leaf of the pinion working on the tooth of the wheel; the others go in and out without touching. B: you see the leaves here are wedged in the teeth, and also touch as they enter. C: you see here they touch as they enter. Having found a part (or made a part) that is the right depth, you mark it. Now, by bending the *other* crossbars to the one which is correct, you will get the wheel true. To find out which way the bars want bumping, place the wheels in the callipers (Fig. 23), and perhaps you will find it wants bumping towards its top; that is, it runs too fleet. Place it on the stake, as shown Fig. 24, which is a piece of tube held in the vice; place your wheel, as shown in sketch, with the pinion nearly touching the back of the shake. The offending bar will then lie across the hollow. Now, if you give the said bar a tap with the tail of a small hammer (do it lightly, or else you will over do it); place it again in the callipers, and you will soon see the effect; strike it close to the pinion. Sometimes you will find a tooth gone out of the wheel. Fig. 22 is the proper way to put in a new tooth. See that the contrate-pinion is free of the escape-wheel pinion.

Third Wheel.—This wheel is managed the same as escape-wheel, but the teeth are put in different.

Fig. 29.—A is a slot cut for the tooth; B is chamfered at bottom and sides; C is the new tooth, which should fit tight and be a little wider than the wheel. Now, if you rivet the tooth, it will fill up chamfer, and will be perfectly firm.

Centre wheel is managed the same as third wheel.

Fusee (or Chain) Wheel.—There are several kinds of fusees; the oldest, I believe, are the visible clicks. The little steel click (or dog) is very easily made. You can buy what is called click-wire; four-pennyworth will be plenty.

(*To be continued.*)

PRACTICAL NOTES ON PLUMBING.—XXX.*

By P. J. Davies, H.M.A.S.P., &c.

FIGS. 158 and 159 will be found described at the bottom of the second column of Chapter XXIX., on page 26.

FIG. 158

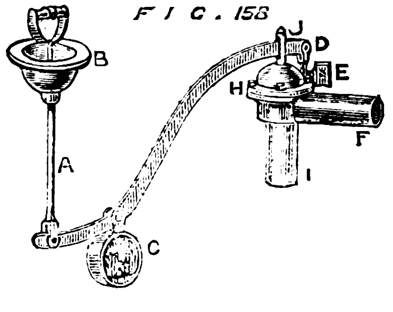


FIG. 159.

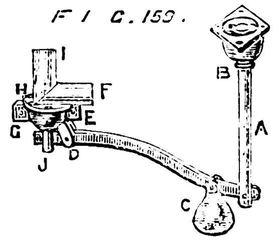

Basement Hopper Closets and Water Supply.

We have now arrived at the class of w.c. that has been beyond doubt very much neglected, so far as the water supply is concerned, for the simple reason that careless workmen will argue that it is only a servants' closet. This argument, however, presents no valid reason why these closets should not be flushed as thoroughly and perfectly as any valve-closets, inasmuch as though they may be in a part of the house not frequented by the upper members, they nevertheless must, if imperfectly arranged, affect the sanitary condition of the house; for wherever foul gases are allowed to escape they must permeate more or less the whole atmosphere throughout the building; and, in fact, if there is to be any difference the servants' closets in the basement should be the most effectually flushed, as foul air, excepting carbonic acid gas, always rises, not descends. A farther reason why the hopper closet should be best flushed is, that the best or valve-closet will work properly if the water is allowed to flow into the basin through an only eighth of an inch pipe, because the basin of the valve-closet quickly fills up by the dribbling income of water, and on opening the large bottom-valve this accumulated water will leave the basin *en masse*, and with a force equivalent to that acquired by throwing down a good pail-full of water: now with the hopper valve quite the contrary is the case, as such feeble, and I may say, inadequate supplies are almost useless; in short, the water should be supplied through a pipe in proportion to the head and valves selected, caution being used to prevent their closing too quickly. I have called attention to this in a former article.

An examination of Fig. 164 will show you the old-fashioned hopper closet-basin L, with a diaphragm cottage-valve V, fixed to a wooden block or brick in the wall; as a rule these basins are fitted with a $\frac{3}{4}$in. supply pipe, and $\frac{3}{4}$in. valve, as at Fig. 160, and with the water supply from a cistern not more than 5ft. or 6ft. above the closet floor-line; such supplies as the above are nothing more nor less than shams. The pipe should be at least $1\frac{1}{2}$in., and a clear way-valve without sharp bends.

---

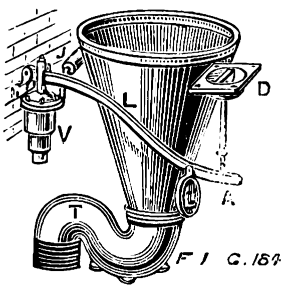

FIG. 164.

Fig. 165 is the cottage-valve V, screwed on to the back-board E; this valve is also shown fitted with the regulator R, which allows the valve-lever to fall slowly. To guarantee the proper working in such instances, it is essential that a proper pull should be selected for this description of levers—i.e., a pull having a long slot for the lever to work through, as illustrated at Fig. 157 A; this allows the lever to drop down without the possibility of its pressing the lever downwards. In fitting the lever to such pulls as these there is one point to be noticed—namely, that you should never allow the lever to rest upon the bottom part of the slot, because if it is allowed to do so the valve cannot properly shut. In proof of this, in the event of the valve allowing the water to run or leak out, examine the lever, and, in many cases, if not most, the above fault will be found the cause. The fault, however, not unfrequently arises from a deposit of lead shavings or solder being deposited in the valve, in which, if you take off the top of the valve you will find the deposit in the seating of the valve; to remove which allow the water to run freely for about two minutes with the top off.

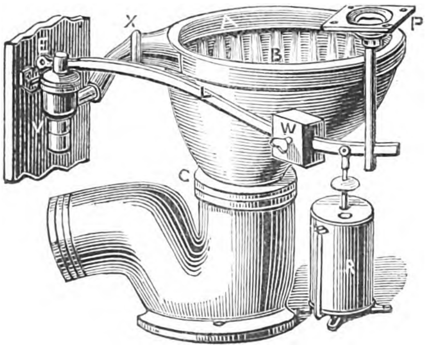

FIG. 165

Stop-Cock Supplies to Hopper Basins.

Years ago it was the usual method to fix a simple stop-cock for the supply to servants' closets, and, in fact, some thousands are so fixed to this day, more especially by provincial plumbers; under these circumstances I think it will be not out of place to suggest the best method to adopt in fixing the same. Fig. 166 illustrates a basin with the description of supply we now have in consideration. J is a fall-down kind of hinged handle, F the cock, B 18in. (or about) of lead pipe from the cock to the arm of the basin, A the putty joint, E the supply-pipe. It may readily be seen that any kind of cock can be used; but those generally selected are ground in. Now, as some of the water companies have raised an objection to the use of the stop-cock for supplying closets, on account of its not being absolutely and thoroughly self-closing, the contingency has been met by bringing into use the "Stool-cock," fitted with a pull-up lever and pull, as shown at D, B, A, 167, or the same end may be accomplished by the use of a self-closing stop or bit-valve, working on either the diaphragm or the falling piston principle.

FIG. 166.

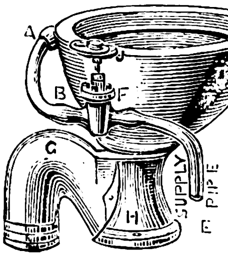

FIG. 167.

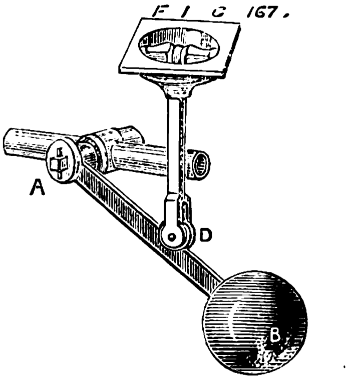


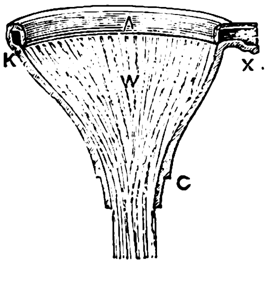
Flushing-Rim and Other Hopper Basins.

Be it most distinctly understood that no matter how good may be the pipes and valves used, unless the spreading arrangements within the closet basin are properly constructed—that is, so that the water shall spread over the whole surface of the basin. There are many methods invented by various manufacturers for arranging this most important point, and most of them are generally effective if properly fitted, so that a great measure of the responsibility rests upon the workman.

The first introduced was the fluted oyster-shell pattern, next the old leaden spreader cut to the shape of half an ellipse; at other times to the shape of a semicircle (see the closet-basin in Fig. 137, also the basin in Fig. 136); after this came into use the copper spreader, tinned over, then the fan with the long screw, fan, nut and union, but now quite out of date.

After this the perforated flush rim, which allowed the water to run out in small streams, as shown at B, Fig. 165 (this kind, I must say, I think, is not quite the acme of spreaders). Last, and not least—for I consider it the best—is the fan or lipped flushing-rim, as shown at K, Fig. 168; also at B, Fig. 169. These basins are a great improvement, and possess considerable advantage over those requiring the lead or copper spreader, inasmuch as if the water supply is plentiful (as of course it should be), the basin will be thoroughly washed, as shown at Fig. 170, and, candidly, I fail to see the want of any better closet. Fig. 171, at C, illustrates a basin fitted with a copper spreader.

FIG. 168.



If you again examine the basin, Fig. 168, it will be easily observed that the water, coming from the fan or lipped-rim, sends a thin layer of water completely over the surface of the basin, and that this layer becomes concentrated. It is very easy to estimate the value of this basin when you consider that at the point of the fan the water is $\frac{1}{8}$in. in thickness, and that as it descends to where the soil is likely to be it gradually concentrates to a thickness of $\frac{3}{8}$in., and finally to $\frac{3}{4}$in. During the last twelve months I have fitted up a great number of this kind, and have found them invariably to act in the way here described.

FIG. 169.

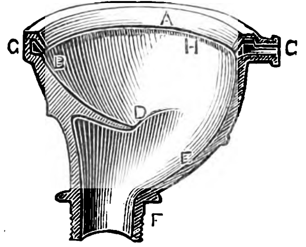


FIG. 170.

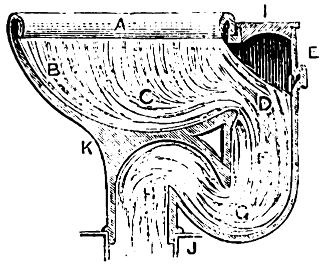

Basins and Traps in One Piece.

Seeing that there are some hundreds of closets that might and are included in this title now in the market, I shall only bring two or three of the most prominent before your notice. Fig. 171 represents one of, if not absolutely, the first made, and is a very good one for the reason that the basin is so constructed that there is always a layer of water for the soil to drop into, which to a great extent tends to prevent the accumulation of soil on the basin. Fig. 170 is also an improved kind of closet basin and trap combined. Fig. 169 is a basin having a lip D, which throws back the water from the front of the basin, and upon the spot where the soil is likely to stain the back part of the closet basin. Fig. 172 is a kind of lip-trap basin; E is a diaphragm which dips into the water, D, and so forms a very compact trap; A is the supply valve fixed upon a floor bracket or frame; K is the connecting pipe from the basin to the valve.

26	11 57 41·54 ,,	2 15 14	13 34 16	2 17 32·22

The Method of finding the Sidereal Time at Mean Noon for any other Station will be found on p. 390 of Vol. XXXIV.

Solar Activity still continues to be manifested, the Sun never being free from spots for a single day. The Zodiacal Light may still be seen after sunset in the west during the earlier part of the month.

The Moon

Is Full at 5h. 46·7m. in the afternoon of the 3rd, and enters her Last Quarter at 6h. 29·9m. a.m. on the 11th. She will be New at 9h. 38·0 p.m. on the 17th, and enter her First Quarter at 6h. 55·9m. in the early morning of the 25th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.
1	13·0	10 42·9 p.m.
6	18·0	1 42·2 a.m.

† A near approach.

Mercury

Is a Morning Star during the whole of April, but is rapidly approaching the Sun, and is very indifferently placed for the observer. He is, moreover, becoming more and more circular in outline, and his angular diameter dwindles from 6·2″ on April 1st to 5″ by the end of the month.

Day of Month.	Right Ascension.	Declination	Souths.
	h. m.	° ′	h. m.
1	23 13·1	7 32·4S.	10 34·4 a.m.
6	23 40·4	4 49·9 ,,	10 41·9 ,,
11	0 9·6	1 38·1 ,,	10 51·4 ,,
16	0 40·9	2 0·0N	11 3·0 ,,
21	1 14·6	6 0·1 ,,	11 16·9 ,,
26	1 51·2	10 15·3 ,,	11 33·7 ,,

Hence Mercury will travel from Aquarius across the whole width of Pisces into Aries. The stars lying in and near his path are all very small.

Venus

Is an Evening Star all through the month, and may be seen very near to the Western horizon after sunset. She is now perceptibly gibbous, but her diameter is relatively small (9·8″ at the beginning of April, increasing to 10·2″ by the 30th), and she is by no means an interesting telescopic object.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	1 21·0	7 31·4	0 41·9p.m.
6	1 44·1	9 56·3	0 45·3 ,,
11	2 7·5	12 15·4	0 48·9 ,,
16	2 31·2	14 27·1	0 52·9 ,,
21	2 55·3	16 30·0	0 57·4 ,,
26	3 19·9	18 22·4	1 2·2 ,,

It will be seen from the above Ephemeris that Venus, starting from about the middle of Pisces, will cross Aries and be found at the end of the month in the confines of Taurus. On April 5th she will be rather less than 1° north of ο Piscium. She will pass rather more than 1° to the north of σ Arietis on the 19th, and 2° south of δ in the same constellation on the 23rd. She will further be in conjunction with Saturn (1° 53′ N. of him) at 7 p.m. on the 19th, and with Neptune at 11 a.m. on the 21st.

Jupiter

Is now too near to the Sun to be fairly visible, a remark which applies, *a fortiori*, to Saturn.

Mars

Is above the horizon during the whole of the working hours of the night; but he is becoming a very insignificant object now, his angular diameter decreasing from 8·4″ at the beginning of April to 7″ at the end of it. He comes into quadrature with the Sun at 5 a.m. on April 2nd, and hence, in a sufficiently powerful telescope, his gibbosity is now very obvious. From the small diameter of his disc, though, his permanent markings are practically undiscernible with small or inferior instruments.

Mars.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	6 53·8	25 12·7	6 13·8 p.m.
6	7 3·5	24 54·4	6 3·8 ,,
11	7 13·5	24 33·5	5 54·1 ,,
16	7 23·7	24 9·9	5 44·6 ,,
21	7 34·1	23 43·5	5 35·4 ,,
26	7 44·8	23 14·2	5 26·4 ,,

The path thus indicated lies (practically) wholly in Gemini, although at the end of April Mars will be found in that part of the sky where Gemini and Cancer are conterminous. He will be rather more than 2° North of δ Geminorum on the 11th.

Uranus

Continues to be fairly well placed for the observer. His angular diameter has imperceptibly diminished from the 4″ of last month to 3·8 this.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	11 7·7	6 29·0	10 31·1 p.m.
6	11 7·0	6 33·1	10 6·7 ,,
11	11 6·4	6 36·9	9 46·4 ,,
16	11 5·8	6 40·3	9 26·2 ,,
21	11 5·3	6 43·3	9 6·0 ,,
26	11 4·9	6 45·9	8 45·9 ,,

Uranus, as thus shown, continues to move slowly away from σ Leonis. From the middle of the month he will be in the same low-power field of view as the small variable star S Leonis.

Neptune

Has now left us for the season.

Shooting Stars

Should be watched for between the 4th and the 11th; between the 19th and the 21st (particularly on the 20th), and again between the 26th and the 30th.

Greenwich Mean Time of Southing of Ten of the Principal Fixed Stars on the Night of April 1st, 1882.

Star	Souths. h. m. s.
β Cancri	7 29 56·79 p.m.
ι Ursæ Majoris	8 10 51·39 ,,
α Hydræ	8 41 25·63 ,,
Regulus	9 21 37·20 ,,
α Ursæ Majoris	10 15 50·63 ,,
δ Crateris	10 32 47·03 ,,
ε Corvi	11 23 15·93 ,,
γ^1 Virginis	11 54 47·97 ,,
α Canum Venaticorum ..	12 9 35·08 ,,
Spica Virginis..	12 37 58·70 ,,

The Method of determining the Greenwich Mean Time of Transit of either of the Stars in the above List for any other night in April, as also that of finding the instant of its Local Mean Time of Southing at any other Station, will be found on p. 392 of Vol. XXXIV.

IMPROVEMENTS IN GALVANIC BATTERIES.

AMONGST recent improvements in voltaic cells, there are few which have more to recommend than that described on page 5 by Mr. Bennett, who seems to have attained a long-sought desideratum—the manufacture in the cell of a product more valuable than the zinc consumed. It is evident that if in any combination for a voltaic cell, we can get the current and produce at the same time a substance of more value than, or as valuable as, the materials used to make the cell, batteries will be able to compete with dynamos. Messrs. J. and S. J. Higgin, of Manchester, proposed to effect this object, but as they did not proceed beyond the provisional stage, presumably they were not altogether satisfied. They proposed to use tin as one element, carbon as the other, with dilute sulphuric acid. In one form of cell they use a hollow cylinder of tin with an inner porous cell containing a carbon rod or cylinder, which is surrounded with granular pyrolusite or manganese peroxide to absorb developed hydrogen. During the action of such a battery, the dilute sulphuric acid produces proto-sulphates of tin and of manganese, which remain in solution in the cell. When it is desirable to renew the exciting liquid, they use the solution obtained from the battery cell in order to obtain such preparations of tin as are required in the dyeing and printing of textile fabrics, and in other industrial processes. To the solution is added a quantity of oxide of manganese, and proto-sulphate of tin is converted into a persulphate. It is then only necessary to dilute the resultant with water in order to precipitate stannic acid, from which other preparations of tin may be obtained by the employment of suitable or ordinary processes. The battery may be varied by substituting a perforated or porous copper cell filled with pyrolusite for the carbon element, and a solution of caustic soda for the dilute sulphuric acid; in which case the spent liquid obtained from the cell will contain stannite or stannate of soda, which may be readily recovered. In another modification a compound solution of nitrate of soda and of caustic soda is used as the exciting fluid for a battery having tin and carbon elements.

An improvement in bichromate batteries, by which they are made to give a "much greater" E.M.F. and constancy has been patented by Mr. T. Coad, of South-street, Finsbury. To a hot saturated solution of nitric acid, bichromate of potash, and nitrate of potash he adds about one fourth part by measure of sulphuric acid, and when cool the solution is fit for use. The exact proportions of the components are not stated.

ELEMENTARY LESSONS IN DRY PLATE PHOTOGRAPHY.—IV.*

Exposure and Development.

A NEGATIVE may be said to be a pictorial representation of any object which shows all the shades of nature reversed. Thus a negative of a landscape, when held up to the light shows all objects, such as the sky, and those which are really white in black, whilst the darker parts are represented by transparent glass. A marvellously short exposure is enough to impress all the details of a landscape on a plate in such a manner that by acting upon the plate with certain chemicals, these details may be made visible. This operation is called development, and consists essentially in strengthing an image, so faint as to be invisible to the eye, till it becomes as vigorous as we desire. Anyone, however unconversant with photographic operations, will perceive that when once we have obtained a reversed picture, we have nothing to do but to place this in contact with a sensitive film, and allow light to act through the negative, to have a picture with its shades true to nature. This latter process is performed with sensitive paper, and is termed printing.

Upon correct exposure and development, nine-tenths of the technical success of negative-making depends, and when once the student has thoroughly mastered the relation of the one to the other, half the battle will be over.

Let the beginner select an object upon which he will make his first attempt. A brightly lighted landscape, with strong contrasts of light and shade, is the best; it need not be picturesque. A suitable view can generally be got out of some window, or a very suitable subject is a bust or statue placed either in a well-lighted room or out of doors. We shall suppose in the present instance that the landscape is selected. The camera should point neither towards nor away from the sun. If the sun shine direct into the lens, the plate will be destroyed; if the sun be directly at the back of the camera, the picture will look "flat." Now, let our student consider the process which goes on during exposure. He knows that when he has his camera with a dry plate in position, and when he has removed the cap of the lens, a perfect picture of the landscape, with all the shades of light, will be thrown on the sensitive film, and that the light will be acting upon it. Now it is evident the brighter parts of the picture will first take effect, and afterwards the darker, until the exposure has been prolonged to such a period that all the shades of light except those which, as we explained, appear in the landscape absolutely blank, will have impressed themselves. At this point the correct exposure has been given. Had a shorter time been allowed, some of the darker shades, or, as it is technically called, the detail in the shadows, would have failed to impress themselves, and the resulting negative would have been said to be under-exposed. On the other hand, had the exposure been prolonged, the light emanating from the apparently black parts of the landscape would have impressed the plate, which would eventually appear to be darkened all over, and would be said to be fogged from over-exposure. It is said of a correctly-exposed negative, that it has all the detail in the shadows without being fogged.

Now we shall show the student how he can tell, by the behaviour of the plate during development, whether he has hit the much-desired correct exposure, or not. He will require to light his dark-room lamp, and to get by him the three flat dishes, the two measuring glasses, all the stock solutions, and his box of dry plates.

Now let him place his camera in position, opposite the view to be photographed; let him remove the cap from the lens, and place his head under the focussing-cloth. Any thick dark cloth or shawl answers the purpose; or a piece of black velvet or macintosh, about two feet square. He should remove the stop from the lens entirely, if it has movable stops, or, if the stops be rotary, should turn them till the largest one is in use. This will make the image on the ground glass very bright, and, by turning the focussing-screw first one way, then the other, he will easily find in what position the image is the sharpest. When he has discovered this, let him place the smallest stop in the lens. We say the smallest stop, not because it is necessarily the best for the picture which he is going to take, but because it will enable him to give a comparatively long exposure.

Having his camera fixed and focussed, let him place the cap on the lens once more, and retire to the dark-room with one of his double dark slides for the sensitive plates.

When once here, he must place the dark slide open in front of the lamp. Now, he must lower the light till there is only just enough to enable him to see. He must open his plate box now and take out two plates—two glasses must be placed in the dark slide at once, but one may be a "dummy" if he happen to have but one dry plate; that is, either a clean plate or a spoilt negative. In placing the plates in the slide, let him be very careful that in each case the side of the plate which appears dull, on account of its having the sensitive film on it, is placed towards the outside. Now, having closed his dark slide and wrapped his plates up again, let the photographer return to the camera. He should carry the dark slide under the focusing-cloth, for further security against light, and in placing the slide in the camera and during exposure should keep the whole apparatus under the cloth for the same reason. He now removes the focusing screen, and places the dark slide in the position occupied by it, keeping the side marked 1 towards the lens. He now withdraws the sliding door, which is the only thing which intervenes between the lens and the sensitive plate. He takes his watch in his hand, and remove the cap from the lens for (say) five seconds, replaces it, slides in the shutter of the dark slide, and carries the latter off to the dark-room. We have supposed any of the usual view lenses to have been used, the landscape to be brightly lighted, the time of year to be spring or summer, and the time of day morning or noon.

---

* Condensed from the *Photographic News*.

MEDICAL ELECTRICITY.*

By Dr. W. H. Stone and Dr. Walter Kilner.

MEDICAL electricity, said Dr. Stone, who read the paper, had been up to now a heterogeneous mixture of loose statements, doubtful diagnosis, and erroneous therapeutics. With hysteria, Metallotherapy, and magnetic appliances, they did not propose to deal. Science is in far too elementary a state to see through these obscure, though real phenomena. Probably, the key to the great enigma of the connection between electricity and nerve force had yet to be found. The bold statement that "electricity is life" is demonstrably false in many particulars. Speaking generally, medical electricity had suffered from its exclusive handling by physiologists and physicians, who might receive valuable help from physicists; indeed, the writers of the paper were actually soliciting such assistance at the hands of this young and active society.

The speaker proceeded to divide the forms in which electricity had been used medically into four, namely—(1) continuous currents, (2) continuous currents made to intermit, (3) induced currents, termed generally "Faradisation," (4) statical electricity. The last of these was the first employed, but it had given the least satisfactory results of any. The third method had been far the most deeply studied. Duchenne's great work on Localised Electrisation early drew attention to this department. That genuine and indefatigable observer was able to point out so many definite diagnoses, and to isolate so many new nervous and muscular diseases by means of the induction-coil, that to this instrument had been given somewhat excessive prominence as a therapeutic agent. Physiologists had also found in it a convenient stimulant for testing the action of nerves and the irritability of muscle; perhaps also the localisation of brain functions. Hence muscular contraction and the action of intermittent currents in alternate directions had been too much relied on as evidence of activity.

Before, however, a single step could be taken in this scientific path, we must have some tolerably accurate mode of measuring the agent we are employing. It is obvious that the units used should be as far as possible those generally adopted in the scientific world. To begin with resistance: This in the human body is singularly great, and is especially located in the epidermis, which, when dry, is an excellent insulator. Wetting it with sulphate of zinc or common salt diminishes this resistance very materially; though even when care is taken in this respect, the residual opposition to a current is large. From hand to hand it is usually about 6000 ohms. In the larger bulk of the trunk, from the sacrum to the nape of the neck, it never, even after long wetting, sinks much under 1,500 ohms. That of the head, from nape to forehead, is about 2,000 ohms. In one case it was more precisely 1,930 ohms, in an adult, and in another, a child, 2,500 ohms. The resistance of different tissues, though not exactly to the present purpose, had been studied by Prof. Eckhard, who stated that muscle was the best conductor, and that this being taken as a unit, cartilage would have a resistance twice, tendons and nerves about 2·1, and bone nineteen times as great. Matteucci states that muscles conduct four times as well as nerves, brain, or spinal cord. The resistance of the skin varies from day to day, being modified by moisture, and by the fulness of the capillary vessels. In a particular case, the positive pole of a battery was placed on the sacrum of a child, and the other on the leg, over the extensors of the foot. By using the same current, and adding quickly a known resistance, the resistance of the body was at first found to be 11,250 ohms, which, on thoroughly soaking the skin, was reduced 2,875 ohms. Three days previously, the resistance before soaking was 13,000 ohms, and after that process sank to 3,000 ohms. Personal idiosyncrasy exercises influence, a delicate skin conducting better than one which is coarse. The face and neck offer the least; the soles and palms the greatest resistance. Disease causes variation of conductivity: the skin over affected muscles in lead paralysis has its resistance increased, while in many old cases of hemiplegia it is decreased to a greater or less extent according to the amount of atrophy which has taken place.

The resistance of muscle in disease is sometimes diminished, sometimes augmented. Augmentation takes place, at the commencement of degenerative changes, from the inferior conductive power of fat to that of healthy muscle. In a case of infantile paralysis, the sound leg had a resistance of 2,500 ohms, the affected leg of 3,250 ohms. In a wasted muscle of many years' standing, the enormous resistance of 16,500 ohms. was reached. It was both easy and desirable to multiply facts such as these.

The second preliminary point was the current which could be borne with impunity. Here results were very discordant. In the three fatal cases from touching the conductors of dynamo-machines, at a music-hall, in the Russian Navy, and at Hatfield, the necessary facts for measurement were absent; although Dr. Siemens had stated that he had often taken a current sufficient to produce a powerful light with impunity. In a case now in St. Thomas's Hospital, a current of 50 milliwebers was borne with difficulty, and one of 20 milliwebers with ease and great benefit. A case of diabetes, recorded by Dr. Stone in the *Proceedings* of the British Association at York in 1881, took about 10,000 microampères, or 10 milliwebers, through his head, from nape to forehead, after some practice; using for its production from 15 to 20 cells of bichromate battery. The particular battery, however, mattered very little; Leclanché's bichromates, and zinc-carbons with sulphate of mercury, all act well, and need not be of large size or small resistance.

In consequence of the high resistance of the skin, it was essential to give a large size to the poles employed for applying the current, &c. Amalgamated zinc, with the mixture of potter's clay kneaded with the solution of common salt, used in physiological experiments, laid over it, was perhaps theoretically, the best; but powdered carbon placed in a bag and immersed in salt and water, answered equally well; or the surgical appliance termed Spongio-piline, a thick felt, backed by indiarubber, through which a well-tinned copper wire was threaded, so as to encompass its whole circumference without anywhere projecting so as to touch the cuticle. The poles could hardly be too large.

A convenient form of Thomson galvanometer with graduated shunts, due to Dr. Kilner, was shown, and also a simple but effective instrument for producing intermissions in the current at any required interval of time. This apparatus consisted of a metronome with contact pieces dipping into mercury cups at each oscillation, a condenser being placed under the instrument to get rid of the extra current, and so to equalise the physiological effect of the making and breaking currents.

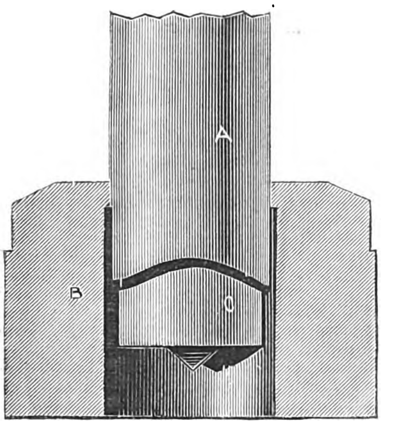
The measurement of induced currents presented considerable difficulties. The Conference at Paris had recommended the use of standard induction coils, but this method does not give any but arbitrary measures. Dr. Stone had tried and showed a vacuum tube, in which the tension of air could be varied by combining it with a barometric column and a movable cistern. This gave a ready means of varying the force of the discharge, by using it as a shunt of variable resistance, and had the interesting results of shunting the "make-current" at a definite point, while allowing the "break-current," which is about six times stronger, to pass between the platinum points; thus obtaining an induced current in one direction only. Latterly he had adopted also condensers of definite capacity charged to definite potentials. The writers were, however, still experimenting with another method, depending on Sir W. Thomson's determinations of spark length. The most practical method at present seemed to be to pass a continuous current of measured strength through an automatic commutator, which at alternate oscillations diverted it in one and the other direction. If there was any real physiological value in rapid reversals of direction, as was claimed by some experimenters, it could thus be secured, without the use of an induction coil. Another form of rotating commutator was also shown, in which an ebonite cylinder, pressed on by six springs, at each quarter-turn connected, first, the condenser to the battery, so as to charge it, and then discharged it through the patient. To obviate the necessity of employing a large battery with the condenser arrangements, Planté's secondary battery could be charged in parallel position from a small number of Grove's cells, and discharged through the condenser in series. In all these contrivances, however, as the current gained in tension, it seemed to lose somewhat in chemical and catalytic power, and to assimilate gradually to the static form.

---

* Abstract of a paper "On Measurement in the Medical Application of Electricity" read before the Society of Telegraph Engineers and Electricians.

DIETZ'S IMPROVED PUNCH.

THE accompanying engraving represents a new form of punch for punching either iron or steel plates, made by R. E. Dietz, of 56, Fulton-street, New York. This punch, says the *American Machinist*, as shown at A, is first turned up to the desired finished size to fit the die B, the same as in making ordinary punches. Then, by a special attachment to the lathe, a peculiar shoulder is turned upon the punch, as shown at C, leaving two high edges and two depressed edges exactly opposite each other. The object of this arrangement is to punch and ream a hole perfectly parallel at one operation. It is accomplished in the following way: The lower part of the punch passes through the iron and pushes out the wad, after which the cutting edge around the side passes through and trims the hole smoothly to an exact standard size. It has been known for years past that the common punch in general use has a very damaging effect upon the iron and steel plates punched by it. For instance, in punching holes for ¾in. rivets through iron plate ½in. thick, the diameter of the hole on the lower side of the sheet will be generally from 1-16in. to 3-32in. larger than the punch.



In punching common iron with the ordinary punch, the iron will be torn so as to leave sharp ragged edges; but in a hole punched with the new form of punch the sides will be found parallel. Another distinguishing feature is that the surface of metal in the hole is condensed, so that it is much harder, and will resist the shearing action of excessive strain upon the rivet even longer than drilled plates, the punching involving much less expense than drilling. This is owing to the fact that a drill does not condense the metal, neither does it cause a flow as is the case with the Jenkins punch. In proof of this statement specimens were cut from the same sheet and tested. One specimen was drilled and riveted while another was punched and riveted. These specimens were then pulled apart in a reliable testing-machine with the following results: Drilled specimen gave way or sheared with a strain of 39,210lb., and the one punched with the Jenkins punch at 39,850, while another punched with the common punch sheared with a strain of 38,820lb.

THE "LONDON" GAS-ENGINE.

A SIMPLE and compact gas-engine, known as the "London," made under Hutchinson's patent, has been on view at the Building Exhibition in the Agricultural Hall. In outward appearance the engine resembles a pillar of cast iron, oval in section, with a flywheel on one side and a pulley on the other. The slide-valve is carried in a casing at the foot, and the whole is mounted on a hollow iron base. The cylinder itself is planted on the base, and occupies the lower part of the pillar or case, the crank working in the upper portion. It will be understood that by this arrangement there is a large air-space all around the cylinder, and following each stroke of the piston a strong current of air passes through the space, thus keeping the explosion chamber cool without the use of water. For simplicity this engine is unexcelled, and as it occupies but little room (a half-horse, 3ft. by 2ft. 4in. on the floor, and 4ft. 11in. to top of flywheel) and requires no lubrication to either valve or piston, it will commend itself to all who have occasional use for "power." The engines are made from one-man up to four horse-power, and a two-man is said to cost only three farthings an hour when working to its full capacity—two-man being the "nominal" power only. The parts are all made to gauge and are interchangeable; they are, with the exception of the flywheel, pulley, and slide-rod, inclosed in the case, and are thus out of harm's way. In fact for simplicity the "London" leaves nothing to be desired.

SCIENTIFIC NEWS.

IN rapid succession we have received no fewer than four Dun Echt Circulars, Nos. 45 to 48, tolerable evidence of Lord Crawford's method of distributing astronomical intelligence. They all refer to the comet discovered by Mr. Wells on March 18, though there appears to be some doubts as to the date. *Science Observer* code telegrams have been received from Dr. J. Palisa and from Dr. Oppenheim. Elements and ephemeris have been received from Mr. S. C. Chandler, jun., Profs. Pickering and Boss, and from Dr. Holetschek, the last being the latest. We give the results in tabular form:—

	C.	P. and B.	H.
T =	June 1·42.	June 15·76.	June 8·51.
π − ☊ =	222° 19′	202° 57′	211° 56′
☊ =	200° 11′	206° 40′	203° 34′
i =	70° 51′	74° 47′	72° 51′
log. q. =	7·7782	9·0257	8·6484

The ephemeris for Greenwich midnight, April 2, is about R.A. 18h 20′; N.D. 41° 58′. Mr. Lohse says the comet is moderately bright, has a straight tail about 6′ long, almost exactly *preceding*. Dr. Oppenheim says the nucleus is tolerably well defined and round, less than 1′ in diameter, as bright as an 8th mag. star, with a tail less than half a degree in length. The comet is increasing in brightness.

Preparations are being made for the observation of the total eclipse of May 17th. The French will probably have two expeditions, as M. Bischoffsheim has promised to pay the expenses of an expedition to Egypt. The most suitable spot for observations appears to be about sixty miles north of Luxor, but the central line passes very near Bagdad and Teheran, where the duration of totality will be half a minute more than at Luxor. It will be seen that there is little choice of spots for observing, and as this eclipse and another that will be visible in Brazil are the only ones during the present century in which the sun will have sufficient altitude at accessible stations for making useful observations of the corona, the opportunity will not be lost.

Prof. E. Ray Lankester, M.A., F.R.S., has been appointed to the chair of natural history in the University of Edinburgh. Sir Wyville Thomson, it may be remembered, resigned this chair last year.

Mr. J. Baillie-Hamilton's new harmonium or reed instrument has been on view at Harrow School, and on Saturday the Premier paid a visit in the company of the Princess Louise. The instrument, it is understood, will be used temporarily in Westminster Abbey. The various stages in the development of this instrument have been described in our pages under the heads of String Organ (see p. 225, No. 685) and Constrained and Free Reeds. The original idea, to vibrate a string by means of wind, by attaching it to a reed, has, we understand, been abandoned, and Mr. Hamilton now uses free-reeds in groups of three, connected by a "bridge," which so modifies the individual tones as to produce a single note of great sonorousness and purity. The defect of the instrument is sluggishness, which may, however, be overcome.

Griscom's little dynamo-machine, or electromotor, which we described on p. 387, No. 823, is now shown at the Crystal Palace, in the Eastern gallery, driving lathes and sewing-machines. The current is obtained from a bichromate battery with large cells.

The Eastern Electric Light and Power Co. have obtained a concession of the waterfall at Penang, and are erecting special machinery to utilise the power for generating electricity for lighting and other purposes.

In an experimental train on the Eastern Railway of France, a Gramme machine, driven by belting from the axle of the guard's van, was found capable of keeping the Maxim lamps fairly incandescent when the train travelled at a fair speed. Accumulators were used for supporting the light when the train slackened or stopped.

A method of increasing the resistance of iron to torsional, tensile, and transverse strains has been patented by M. Séguin, of Paris. The metal is raised to a cherry-red heat, and is then plunged into a mixture of sulphuric acid and water, equal parts. The iron is allowed to remain in this bath until its temperature is reduced to that of the liquid, and is then plunged into hot water.

Edison has patented an electric railway-brake, which consists of a metallic disc, fixed on the axle, and which runs partly between the cheeks of a large horseshoe field-magnet. When the circuit is made, a resistance to the motion of the disc is created and the train is brought to rest.

On Wednesday last, Prof. S. P. Thompson delivered another lecture at the Crystal Palace, this time "On the Electric Transmission of Power," in the course of which he dwelt upon the want of economy in the steam-engine, and the power that might be used for electrical purposes in tidal flows now allowed to run to waste. The subject is an important one, and demands attention for several reasons.

The Institution of Naval Architects held its meetings this week at the rooms of the Society of Arts, on Wednesday, Thursday, and Friday. The papers read were mainly of a technical character, but some have an interest for all workers in steel.

A new method of tempering metals, especially steel, has been brought before the Paris Academy by M. Clémandot. It consists in heating the metal to a cherry-red, compressing strongly, and keeping under pressure till completely cooled. Steel thus acquires excessive hardness, and such molecular closeness and fineness of grain that, when polished, it looks like polished nickel. Like steel tempered in the usual way, it can be permanently magnetised; at least, pieces of the Gower and Ader telephones, magnetised more than three months ago, have kept their magnetism perfectly. Compression being an operation which can be measured, graduated, brought and kept within set limits, one can temper at such and such a pressure, just as one may work with such and such a pressure of steam. M. Clémandot operated with various steels, and found the Allevard steels greatly superior to others. Metallurgists and electricians will doubtless be glad to cultivate the new field which this method opens up.

M. Pianta, manager of the General Company of Telephones in Italy, has the intention of transmitting from Venice to Milan the opera of "Lohengrin," now being performed at the former place. He has introduced improvements into his transmitters, which increase their power considerably, so that they have been used for distances of 120 kilometres (say 75 miles) without diminution in distinctness of the sounds transmitted. The lobby of the Scala Theatre Royal, in Milan (which has the largest stage in Italy) has lately received 92 Edison electric lamps, in place of as many gas-jets. This light is to be extended to the corridors.

The book-production of Germany again increased last year, but only about 1½ per cent. on the previous year, in which 14,941 new works appeared. The total number of books and maps last year was 15,191. Educational literature, and books for young people generally, take the first place with 2,414 works (though this is 32 less than in 1880). There were 1,472 works on theology, 1,469 on jurisprudence, politics, and statistics, and 1,226 on belles-lettres.

It will be remembered that M. Richet lately made some experiments as to how fishes were affected by chlorides of various metals put in the water. He has now tried those metallic solutions on the hearts of frogs. It appears that the toxicity or poisonous effect is not related to the atomic weight, even in metals of the same family. There are notable differences, too, from the results with fishes; thus, nickel, which acts on the gills of fishes less than copper, iron, and potassium, is much more active than these metals on the frog's heart. Copper, which is so dangerous to fishes, has very little effect on the frog. Thus, the opinion is confirmed, that the poisonous effect of a substance varies according to the tissue with which it is in contact. Some of the metallic chlorides stopped the heart in systole (contraction), some in diastole (dilatation). The method by which M. Richet arrives at these results, as also that of M. Paul Bert in another set of experiments (described at the same *séance* of the Paris Academy), relating to the influence of the nerves on the lymphatic system, seem to be of a type with which our physiological schools are happily less familiar than the Continental.

A convenient apparatus for determining the melting point of easily-fused metals and alloys, has been lately described to the Berlin Chemical Society by Herr Liebermann. The commencing fusion of a small column of the substance breaks an electric circuit, so that a bell in the latter stops ringing. The apparatus comprises a beaker-glass with cork cover, through which pass two brass bars, connected at top to the battery and the bell. From their lower ends two platinum rods of unequal length extend down into oil; the ends of these bend towards each other, and support in opposition two pieces of pure graphite, between whose hollowed surfaces is vertically held the small cylinder of metal or alloy. A thermometer fixed in the cover dips in the oil. The beaker-glass is heated from below, and the thermometer is noted when the bell ceases to ring. Herr Liebermann gives numerical results for tin, showing the validity of the method. The melting-point of tin in a stream of carbonic acid and in air, he determined with the same apparatus; the results, though quite available, were not quite so concordant as when oil was used.

The town of Saint Etienne, in France, is supplied by a torrent called the Furens, the waters of which are barred by two dams. It is now proposed by M. Conte-Granchamps to utilise the water-power to drive small Fourneyron turbines, actuating directly some dynamo-electric machines, with a view to providing Saint Etienne, about 8 kilometres distant (say 5 miles), with both motor force and light. The fall is about 133ft., and the daily supply is such as to give theoretically some 617 horse-power, of which a well-arranged turbine would receive two-thirds, or 400 effective horse-power. Allowing for loss by conductors, it is estimated that about 200 effective horse-power would be utilisable at Saint Etienne.

A rich and very extensive deposit of iron, capable of yielding as much as 70 per cent., has been discovered in Lapland.

The Municipal Council of Naples have approved a project presented by M. Lamont, for construction of an underground railway connecting different parts of the town. The line will not be wholly subterranean. Compressed air will be used, and the carriages and tunnels will be lit with gas. The most interesting novelty will be an underground station within the mountain. This station will be connected, by means of a hoist, with an open railway placed above, and serving the villages on the top of the mountain. Between the station at the top and the subterranean station, the vertical distance will be more than 240 metres (say 800ft.)

For the public lighting of Paris 45,815 gas-burners are provided, besides 63 electric lamps, 65 vegetable-oil lamps, and 293 mineral-oil lamps. The total consumption of gas, public and private, in 1880, was 209,915,941 cubic metres. There are eleven gasworks, employing 3,254 workmen, and using nearly 810 million kilogrammes of coal.

The boiling temperature of zinc was estimated at 1040° C. by MM. Deville and Troost. M. Edm. Becquerel, however, obtained the figure 932°, showing a wide discrepance. M. Violle has lately investigated this matter by a new method, and he confirms M. Becquerel's result, the number he obtained being 930°.

Rouen is at present the fifth port in France. The Chamber of Commerce there have lately been considering the question of electric illumination for the quays, which (on completion of works now in progress) will have a total length of about 11,800ft. on the two sides of the river. Careful experiments were made with the Jablochkoff, Siemens, and Sautter and Lemonnier systems; and preference has been given to the last as presenting most advantages with regard to light cast, work expended, and carbon consumed by the lamps per hectare of surface. (Particulars of this competition will be found in *Annales Industrielles*, March 12th.) MM. Sautter et Lemonnier use a continual current Gramme machine and the Serrin regulator.

At the Technical Society of Riga, Prof. Pfuhl recently exhibited a (so-called) jute-velvet, in which a cotton fabric supports a hair-cover of jute. This cloth (produced in a way described in the *Deutsche Ind. Zeit.*) is said to be well adapted for articles of furniture, curtains, &c. It is not attacked by moths.

Mr. Esterbrook, superintendent of buildings in New York, said, in course of a recent examination with regard to the fire at the *World* building, that there ought not to be an iron shutter permitted on any building in the city. The effect of these shutters is to prevent firemen getting access to the fire till it has become a raging, uncontrollable furnace. The shutters might be of use in narrow streets in protecting a building from fire on the opposite side; but they should, in that case, only be closed when danger is imminent. In general, a far better protection is a solid shutter made of wood, and lined on both sides with tin.

We last week referred to facilities enjoyed by the public in Berlin and Hamburg for communication by telephone. A recent report by the Telephone Company of Zurich shows that things are in a still more advanced state in that Swiss town. There are eleven places into which the public may enter, and, for a small payment, converse for a quarter of an hour with any of the subscribers, who are 378 in number, connected with two central stations. Four of these telephone-chambers are in tobacco-shops, two in post-offices, and the rest in sundry shops. Among various other institutions adopted by this enlightened town is the connection of the telephonic system with the central telegraph system. Thus, any subscriber can dictate his telegram to the telegraph employé, and so gain the time which his domestic would otherwise take to convey it to the office. The State realises an economy on the carriage of telegrams addressed to the subscribers. During 1881, there were 8,914 telegrams transmitted by telephone.

The circulatory apparatus of star fishes is one of the most difficult subjects in comparative anatomy, and it would now appear from researches by MM. Perrier and Poirier, that the savants who have studied it have been quite mistaken. The star fish has, in fact, no circulation, properly so called. What was taken for a heart is merely a gland, and the supposed vessels are merely folds of an internal membrane limiting the radial prolongation of the general cavity of the body.

A NEW apparatus for the determination of melting-points has been described by Mr. C. F. Cross and E. J. Bevan. The apparatus consists of a small platform of thin ferrotype iron or silver, having an opening for the reception of a thermometer bulb and a small indentation or depression about 1·5mm. deep and 2mm. in diameter. A very small quantity of the substance is melted in the little depression, and while still liquid a thin platinum wire, bent like an L and fused in a glass float, is immersed in the liquid and held there until the substance solidifies. A thermometer is then inserted in the opening, and the whole apparatus plunged under mercury. The mercury is gently heated, and the thermometer carefully watched. As soon as the substance melts the float rises instantly, and the temperature is noted. Stirring is unnecessary, the whole of the substance is surrounded with mercury, and the attention can be concentrated on the thermometer.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

THE PLANET MARS IN 1881-2.

[19858.]—I HAD not, till this morning, met with any published observations of Mars during the recent opposition; those with which I have just been favoured, through the especial kindness of Sig. Schiaparelli, have surprised me exceedingly; and I hasten to communicate a brief notice of them to your columns. Your astronomical readers are aware that during the opposition of 1877-8 this celebrated observer detected, with an achromatic of exquisite sharpness by Merz, and in the pure sky of Milan, a number of narrow, dark streaks, intersecting the so-called continents, which have been from their aspect termed "canals," though many of them attain the breadth of our Red Sea. These had been seen in part by Green, at Madeira, but not considered of sufficient distinctness or permanence to be admitted into his chart; and, in fact, it was not till after his departure from Madeira that they had been fully recognised at Milan; it has been shown also by Dr. Terby, of Louvain, that several of them have been represented from time to time, in the drawings of different observers. In 1879-80 they were all but one recovered by Schiaparelli, who has given them in a collective map. In the last opposition, when favourable weather compensated for the planet's greater distance from the earth, he not only retraced the whole of them, but found twenty of the number *doubled* by parallel dark lines at a greater or less distance, covering the equatorial region of the planet with a gigantic network; and, in conjunction with some other singular changes, tending to show that the idea of a close analogy between that globe and our earth will not be much longer entertained.

March 28. **T. W. Webb.**

THE SEARCH FOR COMETS.

[19859.]—THE Americans—always foremost—have just commenced a systematic plan of comet-seeking. Hitherto observers have worked independently of each other, and a good deal of useless sweeping has resulted by several observers watching the same regions. This state of things has now been obviated by an arrangement giving to each observer a special district for exploration; in fact the American comet-seekers have been formed into a well organised and efficiently equipped association, which gives promise of most important results.

It is now proposed to begin observations in this country on a plan of somewhat similar character, as soon as the moon has left the evening sky at the end of the first week in April, and I shall be glad to hear from any of your astronomical readers who may desire to take part in the observations. We may be certain, in the event of a new discovery, of valuable assistance from Lord Crawford's Observatory at Dun Echt, where accurate positions would be secured as early as possible.

I have arranged, in conjunction with Mr. A. S. Williams, of Brighton, to examine certain regions, a.m., and p.m., but neither of our positions commands a good view of the S.W. sky, so that unless another observer is found to take charge of this, a most likely region will have to be omitted from scrutiny. **W. F. Denning.**

Ashley-down, Bristol, March 25.

BRIGHTNESS OF STARS—AURORÆ.

[19860.]—I THANK "F.R.A.S." (letter 19508, p. 350, Vol. XXXIV.), for taking so much trouble on my account, and apologise to him for having unwittingly imposed upon him a "weary task." The list he gives from *Les Etoiles* is interesting. At first sight, Flammarion's estimates seem to disagree with Sir J. Herschel's; but as the former has made Arcturus = 1·0, and the latter Capella = 1·0, and as the *difference* between the stars is according to *both* the same, the discrepancies are for the most part easily explained; with the difference of

standard, Flammarion's estimates would, *cæteris paribus*, be about a quarter of a magnitude lower than Sir J. Herschel's. Raising the magnitudes assigned by the French astronomer by ·3, we find that the difference of light between Arcturus and Capella, Aldebaran, Procyon, Altair, ε Orionis, α Persei, respectively, is very much the same now as it was in 1837. (This would seem to indicate that the magnitudes of these stars are unchanged, and that, therefore, they are trustworthy "comparison stars.") But in the case of the following stars, the discrepancies between the measures of the two observers are striking:—

Star.	Flamm. reduced to J. H.'s scale.	J. H.	B. A. C.	Arg.	Proct.	Yarnall.
α And.	1·7	2·54	1	2	3	2 0
α Peg.	1·7	2·65	2	2	3	2·0
γ Or.	1·7	2·18	2	2	2	2·0
Polaris	1·7	2·28	2	2	2	2·0
γ And.	1·8	2·50	3	2·3	2½	2·3
γ Cyg.	2·2	2·63	3	3·2	3	3 0

Are any of these stars, then, variable? It has been suspected that γ Cygni is.

Capella.—I pointed out in my last letter that Sir J. Herschel considered this star slightly variable. The fact that Prof. Pickering (19072, p. 542, Vol. XXXIV.) makes the difference between it and α Persei 1·5, while Flammarion makes the difference only ·9, seems to point to an increase in its light.

β *Tauri.*—In Prof. Pickering's letter, β Tauri and α Persei are rated equal. Sir. J. Herschel made the former ·21 fainter than the latter. I think this star has increased in light since last autumn; at that date, it seemed to me to be distinctly inferior to α Persei; but at present it seems to be rather brighter.

All such instances of possible variation are important, in view of the Astronomer Royal's suggestion that *most* stars may be slightly variable. I had often suspected so myself, long before reading the report of the November meeting of the R.A.S. The Astronomer Royal's plan of a "mean" of many stars being taken, *seems* good; but how is the "mean" to be measured and employed?

Auroræ, 1881, Oct. 23.—At night, very cloudy; when clouds cleared auroral glow could be seen, extending over great part of sky.

Oct. 24.—Auroral glow; similar to, but fainter than, previous evening's.

Nov. 23.—Bright Aurora, which lasted from 6 p.m. to 10 p.m. About 8h. 10m.; the arch presented the curious appearance of being bent downwards a little to E. of the highest point.

Nov. 24.—In evening, auroral glow seen between clouds.

Nov. 25.—Faint auroral glow along horizon.

1882, Feb. 20.—About 9 p.m.; a greenish glow of aurora suddenly appeared in W.N.W., continued three hours, as a bright band spreading far along horizon. Did not send out any streamers.

March 8.—11.12 p.m.; band of auroral light across N.W. horizon.

Glasgow. **S. Maitland Baird Gemmill.**

STAR MAGNITUDES BY SEQUENCES—TO MR. T. E. ESPIN.

[19861.]—If you would explain in detail the method you adopt in estimating star magnitudes, it would no doubt be useful to many readers. Your letter (19554, p. 400) is very interesting, but the expression "simple sequencing" conveys a very vague idea of your mode of working. Do you not need to know the magnitudes of many of a group of stars to begin with? Please give all details. **Opera-Glass.**

ADJUSTMENT OF MIRRORS.

[19862.]—I did not reply to the letter of Mr. Haren (19805), supposing that someone might suggest some means of adjusting the large mirror. I agree so entirely with him that it is an important element, that I was astonished to find that it had been neglected by any of our amateurs. My experience leads me to the conclusion that unless *all* the adjustments are as perfect as possible, the instrument will not perform well. My plan is, to put a stop into the mouth of the tube (say for a 12in. mirror) with an aperture of 11½in. On looking through the adjusting-tube, with the small hole at the eye end, but *not* at the inner end, you see this stop as a thin ring projected upon the image of the mirror. If the image of the stop is not concentric with the image of the mirror, adjust the large cell until it is so. This will have slightly altered the adjustment of the flat. Readjust the flat, and then readjust the large mirror, if the image of the ring is not concentric; in two or three trials you will get your adjustments tolerably exact. It cannot be too strongly impressed upon the minds of the possessors of reflectors that, on fine nights, if the large mirror is good, its definition ought to be equal to that of a refractor. If it is not so, if there is any inequality in the concentric rings, be sure the adjustments are at fault. With mine, a 12in., by Calver, and a Steinheil prism, which is immensely more difficult to adjust than a flat, I have seen, on fine nights, stars of the second and third magnitudes, without a concentric ring—α Herculis, γ Andromedæ, and such like. Some time ago a young friend was in my observatory, and I set the telescope upon Castor. I asked him what he saw? He said, "I see two brilliant round dots." I replied, "Yes; and you couldn't have given better testimony to the beauty of the mirror, and the perfection of its adjustment, than you have given by that remark."

TELESCOPES BY THE "OLD MASTERS."

[19863.]—Will you allow me to ask such of your readers as possess telescopes by the earlier makers to assist me in obtaining particulars of them? Though every year becoming more scarce, there are probably still in existence many fine old instruments, of whose performances we read in the writers of the latter part of the last century and beginning of this?

I may particularly mention the "Beauclerc" refractor by Peter Dollond, with triple object-glass; the 15in. aperture Cassegrain by Tulley; the 5in. apterture refractor by the same maker; Short's 9½in. Newtonian, made for Greenwich Observatory; many Gregorians by Short, Watson, &c.; and last, but by no means least, original Newtonians by Sir W. Herschel. These were instruments, in many cases, of *known excellence*, and often alluded to, and it would be very interesting to trace them to their present possessors.

If, then, your readers will kindly send to me, to the address given below, *as full particulars as possible* of *any* telescopes dating from before, say, 1830, stating (if reflectors) whether mirrors are in their original condition or repolished, and so forth. I shall be very pleased to send, in return, a classified and tabulated list of the information thus obtained to each such correspondent. Details of mounting of mirrors, materials of bodies, form of stand, &c., would also be valuable. May I specially ask the help of Mr. P. Vallance, whom I know to be the possessor of several fine old telescopes?

L. L. L.,
Care of Dr. Woods, Gillingham, Dorset.

OBJECT-GLASSES AND EYEPIECES.

[19864.]—Your correspondent, "Lens" (letter 19795), seems to be in a fog respecting the power of his telescope; let me try to lead him out of it. When he tests his instrument for "power," the object-glass is used simply as a luminous disc; and the image which he measures is the refracted conjugate image of it, formed in the back focus of the eyepiece. The ratio of the diameter of this light-spot to the aperture of the object-glass is the same as that of the foci of the lenses, and therefore gives the magnifying power of the telescope. Used in this way, the object-glass does not perform its legitimate service as an image-former at all; we are simply comparing the magnitudes of two luminous discs, placed at known distances on each side of the eyepiece. When the eyepiece is removed, we cannot compare the focal image with the aperture. Your correspondent is well aware that if he directs his instrument to, say, Jupiter, it makes no difference to the *size* of the image, whether he employs a 1in. stop or the full aperture. His object-glass enlarges the visual angles six times; but this depends on its focal length—not upon its diameter. Let him use a lens of 10in. focus in the same way as the 1in. eye-lens, and he will probably find the focal light-spot to have the diameter he has specified.

I do not think he will find it advantageous to employ crossed lenses instead of planos in a Huyghenian eyepiece; but this, and some other of his queries, must be answered by a practical man. For the Huyghenian combination, the rule for finding the focus of the equivalent lens is: divide twice the product of the focal lengths by their sum. To find the radii, which shall be in a given proportion, and produce any required focus, we proceed as follows:—Multiply together the required focal length, the refractive power of the glass (its refractive index, diminished by unity), and the given ratio increased by unity. The result is the longer radius. Divide it by the given ratio, and we obtain the shorter curve. As an example, suppose we have some flint glass, whose refractive index is 1·6, and that we require to form a lens of 4in. focus, having its front radius three times the back one. Here we have $4 \times (1{\cdot}6 - 1) \times (3 + 1) = 9{\cdot}6$; and 9·6 divided by $3 = 3{\cdot}2$, the shorter curve. This rule applies to a double convex or double concave; but if one surface only be concave, we must make the numerical value of our proportion negative, and the convex radius must be greater or less than the concave, according as the focus is required to be negative or positive.

From your correspondent's second letter, it would appear that he has some very misty notions regarding foci. I can only counsel him to read, and thoroughly master, some good elementary book on optics, such as Chambers's, or others. I will send a paper on calculating the foci of lenses, which will need a fair knowledge of arithmetic and a slight knowledge of algebra only. Beyond this I cannot assist him. An acquaintance with the elementary principles of a science must be obtained from some of the recognised textbooks, and the extent of mathematical knowledge which I have indicated is absolutely necessary to anyone who would wish to perform even the simplest calculations regarding lenses. **Orderic Vital.**

DR. HASTINGS' METHOD OF MAKING AND TESTING FLATS—CLEANING MIRRORS BEFORE SILVERING.

[19865.]—In my letter (19763), on Dr. Hastings' process of making and testing flat surfaces, a serious error occurs in the first column of page 593, and in the 26th line from the bottom, where the types, or, may be, my own manuscript, makes me say, that the polisher should be from ¼in. to ⅛in. less than the glass to be polished. It should read—from *one-quarter to one-eighth less than the glass*, without reference to inches, as it is entirely proportional. If we were making a 4in. flat, then the polisher should not be larger than 3½in. and may be as small as 3in. This might be inferred from what is said at the head of the second column; but it would, even then, seem paradoxical. I was pleased to see in the same issue of your paper, that Dr. Steinheil had furnished M. Houzeau a *perfect* plane for determining the flexure of telescopes. No doubt it was made in the same way as mentioned in letter 19763. Your readers must not think me slow in correcting the above error, as I have just received your issue of the 24th of last month, and to-day is March 10th, and it will be a fortnight before this reply will reach you. A note in reference to cleaning mirrors for silvering. Mr. Geo. Clark, of Alvan Clark and Sons, told me he never used nitric acid, only when he had to cut off an old film; but cleaned them with a solution of potash in water, and the *palm of his hand*. I have done a great deal of silvering lately, and have discarded the nitric acid entirely, using a solution of, say, 1oz. of pure potash in 12oz. or 15oz. water, and, as I don't care to risk the palm of my hand, nor do I care to risk that dangerous tool, a test-tube stuffed with cotton, I make a pad of cotton flannel filled in with good, clean cotton, leaving the soft side of the flannel outside. A good large pad can be made, and is a capital article for cleaning with. Pour a tablespoonful of the solution on the mirror; rub thoroughly; rinse off pretty well, though it will do no hurt if it is not thoroughly washed off; and with ordinary care you will have a clean mirror without those unpleasant nitric-acid fumes, that at best are "a thing of beauty, and a *smell* for ever."

Jno. A. Brashear.

Pittsburg, Pa., March 10th.

MICROSCOPICAL CLUB.—TO "H. C. S."

[19866.]—I shall be very pleased to assist in forming such a society as you mention in letter, p. 615, Vol. XXXIV. If you will communicate with me by post, we can exchange suggestions, &c., and devise means for practically starting such a society.

I should be much pleased, at the same time, to see a similar society for amateur photographers started in connection with the readers of the "E. M." If any feel inclined to help, please write to me, with suggestions, &c., and we will commune one with another about it. I advertise my address in the Address Column. **F. C.**

TESTING THE PURITY OF GUANO.

[19867.]—In 1877, being engaged in the collection of diatomaceæ, I turned my attention to those contained in guano. After much difficulty I obtained half a dozen samples of pure guano, through a friend connected with the trade, and having subjected them to the ordinary process, modified in the manner I will describe, I took the mean quantity of diatoms contained in a measured quantity of each sample as a standard.

(1) One drachm of the guano is agitated with a gallon of water and allowed to stand 3 hours, and the water poured off.

This is repeated; and should the water be much discoloured after standing the second time, the sample is impure.

The water being then poured off, the sediment is put into a large test-tube, by washing out the vessel in which it was contained with portions of 3oz. of water. When the whole three ounces with the sediment is in the test-tube, it is then well shaken and allowed to stand one hour; the water is then poured off.

(2) Add hydrochloric acid (fort) to the sediment till effervescence ceases; then pour it off, add half an ounce of fresh acid, and boil for two hours.

(3) Wash again as in (1).

(4) Repeat 2, substituting HNO_3 for HCl.

(5) Repeat (4); then pour off the three ounces of water after standing one hour; add one ounce of water to the residue; stir briskly with a glass rod, and while the sediment is in motion, place one drop on a slide, spread out with a needle, and dry with a gentle heat. Six slides being thus prepared, the mean quantity of diatoms is compared with the same quantity in the pure standard sample. The result is the quantity of pure guano in that under observation.

Each step in this process is a rough analysis of the guano; the purity is in proportion to the absence of colour of the water after washing.

The greater the effervescence with HCl, the more phosphates, &c., especially soda and calcium.

With HNO_3 the more potash.

The character of the coscinodisceæ and other forms are different from those contained in other substances—*e.g.*, I never found G. biseriatæ, but the variety of coscinodisceæ is greatly in excess of what is found in infusorial earth. Campylodiscus is rare. Surirella is comparatively rare; in fact, on comparing photographs of diatomaceous deposits there is a distinct difference in the general distribution and character of the diatoms.

I have examined several hundred samples supplied by friends, and though the process seems complicated, yet it is easy to carry out, and one hundred samples are almost as easy to manipulate as one.

In every case in which my advice was followed as to the qualities of a sample, the result was satisfactory. I will give one example of the frightful consequences of adulterated guano. A relation, an extensive landholder in the west of Ireland, sent me a sample. I reported favourably upon it, and he undertook to supply it to his own tenants in small quantities; that year's crop was good. Having perfect confidence in the firm, he gave a large order the following year; put it out without testing. The result was disastrous, and as its previous success increased its sale to nearly the whole of Mayo, the consequences were worse than if it had only been an original bad sample. A portion of the second guano supplied was sent to me; it contained 1 in 2,000 of pure guano. A lawsuit took place, and all sides lost heavily by the transaction.

I never would have thought of applying the method had I not been informed that no analysis was capable of telling the quantity of guano in any sample.

I have only found seven tolerably pure samples in some hundreds.

A. Cowley Malley, B.A., M.B., &c.

COLD SOLDERING.

[19868.]—Various nostrums have been proposed from time to time which profess to be reliable methods of soldering without heat; but when tried they have generally proved useless.

The following recipe, which is due to Mr. Fletcher, of Warrington, will, I think, be found to be more trustworthy.

It must be borne in mind that, though the first preparation is tedious, a large quantity of the materials can be made at once, and the actual soldering process is as simple and quick as it well can be.

Flux: One part metallic sodium to 50 or 60 parts mercury. (These combine on being well shaken in a bottle. If this is too much trouble, the sodium amalgam can be bought, ready made, from any chemist or dealer in reagents.)

This sodium amalgam must be kept in a stoppered bottle closed from the air. It has the property of amalgamating (equivalent to tinning by heat) any metallic surface, cast iron included.

Solder: Make a weak solution of sulphate of copper, about 1oz. to one quart of water. Precipitate the copper by rods of zinc; wash the precipitate two or three times with hot water; drain the water off, and add for every 3oz. of precipitate 6oz. or 7oz. of mercury; add also a little sulphuric acid to assist the combination of the two metals. When combined, they form a paste which sets intensely hard in a few hours, and this paste should be made, whilst soft, into small pellets.

When wanted for use, heat one or more of the pellets until the mercury oozes out from the surface in small beads; shake or wipe them off, and rub the pellet into a soft paste with a small mortar and pestle, or by any other convenient means, until it is as smooth and soft as painter's white-lead. This, when put on a surface previously amalgamated by the sodium and mercury, adheres firmly, and sets perfectly hard in about three hours. The joint can be parted, if necessary, either by a hammer and cold chisel, or by a heat about sufficient to melt plumber's solder.

Where expense is no object, Mr. Fletcher gives a recipe for a much stronger solder, which will set hard in 15 minutes. **Glatton.**

GRATIS ADVERTISEMENTS—NEW BATTERIES—CAUSTIC SODA.

[19869.]—On page 61 (19811) is a sketch of an electro-plating apparatus, together with an announcement where it may be seen and obtained. The next letter contains a sketch of a new battery, with an accurate and concise description of its construction. Now, doubtless Mr. Tolman will make HIS battery for sale; but he does not on that account merely send a sketch, and say where it is to be obtained,—he gives instructions which will enable anyone (if so inclined) to make it, and he reserves his business communications for an advertisement. He does not even append his address. Not so Mr. John E. Chaster, who says that his apparatus is very good and something new, but he leaves out how it is made; he tells us what is not required in his battery, but forgets to say what is wanted; and if he occupies the correspondence columns with a gratuitous advertisement, he should feel himself bound in all honour to give an accurate and good description of the whole affair and method of construction. As it stands, his letter is an advertisement pure and simple, and he should have sent it as such. I should not, perhaps, have noticed it so much were it not for the contrast between his letter and that of Mr. Tolman, who deserves the thanks of English Mechanic readers for his disinterested and valuable information, and I hope he will lose nothing thereby. As a rule, those who make their own batteries would not have them at all if they could not do so. That is just my case.

While on the subject of new batteries I will mention that I have just re-perused the details of Mr. Bennett's new cell, and would also advise "W.H.G." (46446) to read it again. He will there find that it is not stated that potassium hydroxide and caustic soda are the same thing—either will answer the purpose. Caustic soda is the cheaper preparation; but as there is no general use for it, it is not, as a rule, to be obtained retail. I would recommend him to try what is called "soda ash." I can't say whether it will answer as well as the purer preparation. A solution of caustic soda can be prepared by boiling together a solution of common washing-soda and some freshly slaked lime; an iron saucepan will do, and it will not injure the saucepan; say, 1¾lb. washing-soda, and ¾lb. slaked lime, boil in a quart of water for ten or fifteen minutes, allow the sediment to subside, and pour off the clear solution of caustic soda. This can, if necessary, be concentrated by evaporation. This quart of solution will contain between six and seven ounces of caustic soda, and will not cost more than 2d. to make. **Os.**

MAX ROSENFELD'S LECTURE EXPERIMENT.

[19870.]—At p. 51 of your last issue, you describe a very ingenious lecture experiment devised by Max Rosenfeld for showing, without the aid of a chemical balance, the increase of weight attending oxidation. In the course of your description you say: "The foil with its load is carefully removed, and held over a flame until the iron is converted into oxide. When cold, it is replaced on the glass cup, and causes the instrument to sink until the cup almost touches the water." A far more effective way of performing the experiment is to make a little mound on the foil, if iron, carefully reduced from the finely-powdered oxide at the lowest possible temperature, and then to apply for a moment the light of a taper to the extreme top of the mound. The iron will begin to oxidise at the point of application of the flame, and the oxidation will spread through the whole mass of the metal, notwithstanding that the taper has been removed; the hydrometer will sink the while. This method of performing the experiment is not original, but it may be new to some of "ours."

Alfred W. Soward.

THE EVOLUTION OF THE TELEPHONE.

[19871.]—On the 23rd inst. Professor A. E. Dolbear, of America, delivered before a crowded audience, at a meeting of the Society of Telegraph Engineers, a lecture "On the Development of a New Telephonic System." Starting with Page's early observation, that a bar of soft iron, when surrounded by a coil of wire conveying a current of electricity, emitted a sound whenever the circuit was made or broken; and that by the use of an automatic make-and-break sounds of a definite pitch could be obtained, Professor Dolbear traced the successive steps in the Evolution of the Telephone.

Passing from Page, the first name met with is that of Farrar, who constructed an electric telephone capable of transmitting sounds of different pitch. He modified Page's apparatus by the employment of a series of vibrating reeds as contact-breakers, and was thus able to transmit tunes, but he failed to transmit articulate speech. Next came Helmholtz, who, using a tuning-fork as contact-breaker, sent timed electric impulses through a wire, at the other end of which was an electro-magnet having for its armature a tuning-fork similar to that used as the contact-breaker. The electro-magnet being magnetised and de-magnetised synchronously with the making and breaking of contact, the tuning-fork at the receiving-station was caused to vibrate in unison with that at the transmitting station. By using many tuning-forks sounds of different pitch could be transmitted: musical notes, but not speech. After Helmholtz came Reiss, the merit of whose work has too frequently been under-estimated. It is well known that in an electrical circuit, where a contact-joint occurs, the current flowing depends upon the nature of the contact. Every beginner knows that to get his battery to work properly he must clean his binding screws and tighten them up well. This fact was applied in Reiss's transmitter. A small plate of platinum was attached to the centre of a diaphragm capable of vibrating, and placed in connection with one pole of a battery. A platinum point connected with the line-wire was placed in delicate contact with the platinum-plate. A current flowed through the line. On speaking to the diaphragm, the latter was thrown into vibration, the amount of contact between the platinum-plate and point varied, and consequently the current flowing through the line varied; an undulatory current was produced. Reiss at first employed Page's iron bar, mounted on a resonant base, as a receiver. The magnetism of the bar varied exactly as the current varied, and if Reiss had but discarded his clumsy apparatus in favour of apparatus of more refined construction, he would have succeeded in transmitting speech. Subsequently (in 1863) he adopted another form of receiver. The line wire was attached to an electro-magnet, before the pole of which was fixed an iron diaphragm. With this improved apparatus of Reiss', Prof. Dolbear has been successful in transmitting articulate speech.

In 1876, Prof. A. G. Bell, bearing in mind the truth that when a magnet is moved so that its lines of force are cut by a closed conducting circuit, a current is produced in that circuit, conceived the idea of speaking to the armature of an electro-magnet, which, of course, is itself a magnet by induction, and of listening at the armature of another electro-magnet placed in the circuit. He reasoned that the electromotive force caused by the motion of the armature of the first electro-magnet would cause a variation in the strength of the second electro-magnet, which, in its turn, would set up a vibratory motion in the armature of that magnet. He was successful in his experiment. The same year Prof. Dolbear suggested the use of a permanent magnet in place of the electro-magnet. This also was successful. But neither the Bell nor the Dolbear transmitter was sufficiently powerful. It was found necessary to return to the Reiss transmitter, which, however, had the disadvantage that its platinum was very liable to break and to fuse. Edison soon greatly improved Reiss' instrument by substituting plumbago, and afterwards lampblack, for the platinum of the original instrument; and Hughes, later on, perfected it by the further substitution of unconstrained gas-carbon for Edison's lampblack.

It is known that a Leyden jar, when charging or discharging, gives song. In 1863 Sir William Thomson noticed that the air-condenser used in connection with submarine cables, when charging or discharging, also produces sound. Dr. Wright and Mr. Varley have made somewhat similar observations.

When a current is sent through an electrolyte, decomposition takes place, and the evolved gas exceeds in volume the liquid from which it was produced. By varying the current the amount of gas evolved can be varied. By connecting two plates, one free to vibrate, with the poles of a battery and bringing them parallel to and near to one another with a film of electrolyte interposed, it was found that, when used as a telephonic-receiving instrument, the variation of amount of gas evolved produced variation of pressure and threw the diaphragm into vibration. Sound could be reproduced. But it was found that sound could be reproduced when there was no electrolyte in the apparatus. The explanation of this was not far to seek.

If an electrical machine is joined to one end of a wire, and a plate to the other, and a pith ball is suspended before the plate, whenever the machine is worked the ball is attracted. If the ball is substituted by a thin flexible plate fixed at its edge, that plate will be thrown into vibration, and if these vibrations are rapid enough, sound is emitted. But this arrangement is a condenser. To produce the maximum sonorous effect, the plate must have a certain amplitude of vibration; therefore packed condensers are bad. There must be no electrical absorption; therefore there is a limit to the size of the plates, and practice shows that small ones are best.

If a fixed point connected to a frictional electric machine is brought near to a diaphragm free to vibrate, and connected to a line wire having at its other end a Dolbear receiver, then on working the machine sparks will spring from the point to the diaphragm, and a current of high tension electricity will flow along the wire. On speaking to the diaphragm, the air-space will be varied, and consequently the current flowing through the wire. Substituting the secondary current of an induction coil for the charges of the frictional machine, and throwing a Reiss transmitter into the primary circuit of the coil, a telephonic apparatus is obtained, wherein the ordinary conditions of the electrical circuit are not necessary. The second plate of the receiver need not be joined to earth specially. It may even be dispensed with, when the instrument will work by virtue of the induction of the remaining plate upon the rubber case containing it. More surprising still, the line wire may even be cut, and although there is no connection with the receiver save through the air and surrounding objects, speech is still transmissible. It is sufficient to lead the end of the line-wire into a room, and anyone present may pull out his own pocket telephone, and, standing 50ft. away from the end of the line, hear everything that is said at the other station.

The resistance of the coil employed is about 2,800 ohms; the battery is a small bichromate cell. Speech has been transmitted through a line 256 miles long in rainy weather, and no induction troubles have been experienced.

Prof. Dolbear claims for his system that in its principle it is a distinct advance on that of Reiss, for whereas in the latter vibratory motion of the diaphragm produces alteration in the current which induces magnetism, which in its turn produces vibratory motion of the receiving diaphragm, in his own the alteration in the current directly produces the mechanical motion of the diaphragm.

Alfred W. Soward.

ORNAMENTAL SLIDE-REST.

[19872.]—I AM now about to describe a slide-rest which I have fitted up as an ornamental one for my lathe, but which, for those who only possess light lathes without back-gear, is capable of being used for light metal and wood turning as well, and for the latter purpose is a much better pattern than that shown in all books on turning, as the regular ornamental rest, and is just as convenient for ornamental turning. Fig. 1 is a general view of the rest; an ordinary fluting-stop, A, is shown in position at one end of the main slide, and there should, of course, be another provided to go on the other end; these consist of a brass casting chamfered underneath at each side to fit the slide of rest, so that it can be slid along to any part of it, and to which it can be clamped by the two vertical set-screws shown. The use of these stops is when fluting a piece of work with the drilling instrument or universal cutter in the tool-holder, they are set so as to limit the travel of top slide on bottom one, which travel can be nicely adjusted by the horizontal screw with milled head, and so make all the flutes on the work of the same length, if desired. The depth of cut is regulated by a simple form of stop, fitted to the top slide. It consists of an arm, B, which has a hole drilled through a boss at one end, to fit accurately on the rounded end of leading screw, but moves freely on it until clamped by the set-screw D. C is a steel rod which slides rather stiffly in a hole drilled through the side of seat of top slide. The way to use this stop is, the set-screw D being slackened, and the arm B resting on end of rod C, the first cut is taken by turning the leading screw E (which is left-handed in my rest) by a winch-handle not shown. When the desired depth of cut is taken, the set-screw D is tightened, which causes the arm B to revolve with the screw E, and the rod C is then shifted, so that on reversing the motion of screw E, the end of arm B will just clear end of rod C; but when the next cut is taken, the end of B will catch on C when the same depth of cut is reached, as E travels with the top slide while C is fixed. This is a form of stop which has not been given in any book on turning, to my knowledge, but is a thoroughly satisfactory one. The main, or lower slide, has on its upper face a scale of 20ths of an inch, which, to my mind, is preferable to having a divided head on end of leading screw, and allows you to have the leading screw of any pitch you like. The tool-holder G is a very convenient and efficient one: it swivels round to allow of the tool being set at either side or end of top slide, being clamped in position by the nut shown on top, and the tool then clamped by the two set-screws with square shanks. I may here mention that I have made all the set-screws, both in tool-holder and fluting stops, to fit the winch-handles which turn the leading screws, so that they act as spanners, and the winch-handle can be applied to either end of main leading screw F. Both my leading screws are ½in. with V threads, and are left-handed, though I don't think there is any particular advantage in having them so, and there is the disadvantage of requiring a special tap for the nuts; however, it is usual with lathe-makers to have them left-handed. The nuts are gunmetal, and in order to be able to take up any backlash caused by wear, they are made like H, having a lug cast on the side of them, which after the nut is drilled and tapped is sawn through, and a small screw is fitted through the two jaws thus formed, as shown in the cut H. and when it is desired to take up any end-shake the top slide is moved until the hole I comes over the little set-screw in nut, when, with a small screw-driver, the screw can be tightened and thus grip the threads of the leading screw tightly, for which the V threads are better adapted than square ones. There is a similar hole through bottom of lower slide for the purpose of adjusting its nut. Thus any wear caused by the strain of metal-turning can be fairly compensated for, and when the nuts get too much worn for ornamental work, they can be replaced for a few pence, as the gunmetal nut always wears and not the steel screws. The lower slide of this rest has a pillar projecting from it underneath, which is turned accurately to fit a socket in the sole, like that of a T-rest, and can be clamped in any position by the set-screw J. The top of this socket is graduated, so that it shows the angle at which the slide-rest is set, and there are marks by which it can be set true, either parallel or at right angles to the lathe-bed. If the rest requires to be set higher than usual, a washer of the required thickness can be slipped on the pillar, which is a steadier way than raising it by means of a screw-ferrule, as suggested in some books. The sole-plate casting should be made much longer than would be required, if only ordinary turning tools were used in the rest, as instruments like the eccentric and rose-cutters project much further than such tools. For want of space I have not shown the sole-plate in my drawing as long as it ought to be. The holding-down bolt, Fig. 4, has a cradle which has a tenon, L, that fits accurately between the shears of lathe-bed, and at right angles to it on top, two shears, K K, between which the sole-plate of rest slides without shake, and the ends of which shears rest on lathe-bed; the top of bolt has a flat oblong head which engages in a T-slot in bottom of sole-plate. The rest of the bolt, with its washer and nut, speaks for itself. This cradle is not absolutely necessary, as the sole-plate can always be set at right angles to lathe-bed by means of the blade of a square laid across; but of course tho cradle is more convenient. Fig. 2 is an end view of rest when arranged for what is called curvilinear work; and Fig. 3 is a top view of same arrangement. The upper leading screw of rest is removed by taking out the two binding-screws in its collar and unscrewing it out of its nut, and the slide is advanced instead by a lever M, Figs. 3 and 5, which has a slot that is placed over the stud N, Figs. 1 and 2, and which lever has a pillar O, Fig. 5. riveted to it, which fits into the hole P, Fig. 1. Q, Fig. 2, is a plate screwed on in place of the collar of leading screw, and through it is tapped a screw R with a milled head; the point of this bears against the edge of the sheet-brass template S, Figs. 2 and 3, which is secured to bottom of lower slide by a screw T at both ends. The edge of this template is cut into the desired shape of the outline of the work, and by keeping the tool pressed up to its work by the lever M, and at the same time turning the lower leading screw by its handle, the point of the screw R, Figs. 2 and 3, will follow the outline of template S, and, of course, the tool will also follow the outline of work which is chucked on mandrel of lathe. It will thus be seen that a piece of work, say a vase, can, with the universal cutter, be fluted horizontally (as it appears on lathe-nose) from top to bottom, provided your template is properly cut, which can be done by drawing the outline on a piece of paper and pasting it on the sheet-brass, and then filing out to shape. This slide-rest is not at all hard to make, as the castings can be got ready planed, requiring very little to de done to them in the way of getting the surfaces true. And the fitting of it up is, to my mind, far pleasanter work than doing the most elaborate ornamental patterns on wood or ivory, though I like all branches of turning. Would Mr. Evans give us an article on ornamenting curves with the dome chuck, as I have only used mine in producing and ornamenting squares and polygons.

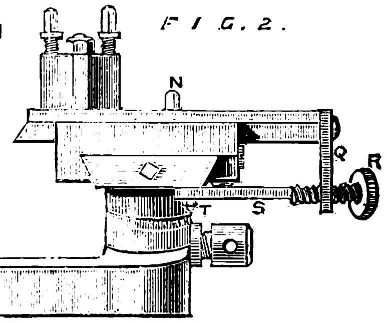
FIG. 2



ORNAMENTAL LATHE-THREADS.

[19873.]—IN answer to "A Member of the Amateur Mechanical Society," 19831, I shall have great pleasure in answering his courteous request to the best of my ability, with regard to the nose of the mandrel on the lathes I am now making. I may almost say that there is scarcely any standard in particular, inasmuch as I make many different kinds. The old so-called standard 9·45 has been used for many years, but I always make them larger in diameter, viz., 7-8in., but I am now making several with an aliquot thread 10 to the inch, and the same diameter; I consider the original diameter, ¾, too small, considering the strain they at times have to bear. I have also some ordered to be made with a ⅞ Whitworth thread on the nose. I merely mention this as an example of the fact that there are various opinions upon this now important subject. I have for some time decided to gradually substitute the 10 threads in place of the 9·45; but I may point out that as all chucks ought to be made on their own mandrel, it does not materially matter, considering the means of cutting the chucks are provided in the shape of a taper and plug-tap, and I fear, from the remarks I have seen, that those who are possessed of these labour under the impression that the plug is intended to follow the taper. As a matter of fact, the taper is simply to mark off the thread as a lead; it should then be chased with an inside screw tool till the plug will just pass up the chuck. In other words, the last tap forms more of a cutting gauge than anything else. The diameter of the half-round bit used for finishing the hole should be rather smaller than the bottom of the thread, so as to allow a little for chasing. I trust our correspondent will find this sufficient for his purpose. If not, I shall be pleased to go more fully into the matter. **J. H. Evans.**

[19874.]—I REGRET that pressure of occupations, which, as I have before said, precludes my carrying on a correspondence, together with absence from town, have hitherto prevented me from endeavouring, in a concluding letter, to give Dr. Edmunds the final information he has courteously requested in your issue of the 10th inst.

1. The diameters of the external screws at the bottoms of their threads, to arrive at the sizes of the drills for the apertures for the taps? For this purpose every set of the taps and dies in question is provided with a corresponding and hardened gauge-plate, having a series of holes tapped with the plug taps. These screwed holes give the diameters asked for, with sufficient precision for practical purposes, and they will, in like manner, give the diameters of the drills. These latter, it may be said, should barely touch the threads in the gauge-holes, for the smallest screws have gradually more clearance with increasing sizes, until in the larger there may be a difference of, say, from two to four hundredths. What is required in all tapping is that the holes should be bored to receive the small ends of any taper or entering taps to a depth about equal to their diameters; this is easy of accomplishment, and the above general directions are both sufficient and more serviceable than a didactic list of diameters of the drills, which also, as everyone knows who is acquainted with the subject, would be incomplete for theoretical service, unless a digest of voluminous data as to the practice upon different materials, upon drilling and broaching tools, and the compressing and cutting action existing in different degrees in all taps and dies—all subjects of considerable interest. The diameters at the bottom of external screws may be calculated from those at the top mathematically; and there is another and perhaps readier method that is not without convenience, which is to turn down two or three threads of any screw of a known external diameter until they just disappear, and to measure the resulting cylinder.

2 and 3.—Shallow-thread screw-tools of all the previously-mentioned twelve threads are made and kept in stock. They are principally used for striking and chasing screws by hand or with the traversing mandrel, and either for the friable materials or for the harder or more compact, when of forms of thin tube-like character, many of which are met with in ornamental turning. Less frequently used in the diestock, both taps and dies are then necessarily of the shallow thread, and have corresponding gauge plates; therefore, supposing two bolts of the same external diameter, one of deep and the other of shallow thread, it is sufficiently evident that the aperture to be made for the tap for the latter would be larger than that for the former, from the difference in depth of thread, 60° instead of 50°. The small and nearly cylindrical end of the taper tap will again give its size.

On reperusal of a former letter, No. 19747, I find that Dr. Edmunds describes the attempt to cut a shallow internal thread in cast iron to fit an external deep thread, viz., the nose of a mandrel; this proceeding would be injudicious, because, as will be at once seen on drawing a rough diagram, from the difference of angle, only the extreme points of the external deep threads would be in contact with the internal shallow thread. The use of the shallow screw tool escaped me in my reply, and I should have explained the more correct course of action as follows:—The aperture would be bored a trifle larger than for brass or gunmetal, or bored the same size and then slightly enlarged with a turning-tool in the slide-rest, the enlargement in either case being but little, not to interfere with the action of the smaller or entering lathe tap in scoring the internal thread. The deep-screw tool would then be used, and when the thread was sensibly formed, but before it was cut up, the turning-tool would be again resorted to, to again enlarge the screwed aperture, so as to leave the taps of the threads truncated when finished by the subsequent use of the screw-tool.

4. The external diameters of the 5in. and 6in. centre-mandrel noses have already been given; premising, however, that such diameters may sometimes suffer accidental interference, the dimensions of the series asked for should be as follows:—4in. centre ·75, thread No. 4; 5in. centre ·8125, thread No. 3; 6in. centre ·9375, thread No. 3; and 7in. centre 1·125, thread No. 2. Some small variation in the diameters of the half-round bit used for the entering-taps is of no practical importance, while, as above mentioned, it may sometimes be resorted to; for general use with the above, it may be said that they do not exceed ·625 for the two first, and ·75 and ·95 for the two last, respectively. It should be mentioned, however, that 4in. height of centre so restricts the capacity of the apparatus and dimensions of the work that may be produced, that it cannot be recommended for ornamental turning, for which purpose also, for other reasons, the 7in. centre is as unsuitable.

My replies have been written simply for the pleasure of giving your correspondent the information he has asked for, much of which, being already within his reach by the exercise of a little thought, it is only fair to presume he only desired for confirmation; but I would now assure him, and without reference to any particular series of threads, that he will find in practice that nearly every difficulty as to convenience in repairs he can imagine will still exist with any. Screwing chucks to fit the mandrel is an operation of careful fitting, more under control with the lathe-taps than by other means, and the feat of damaging the nose of a mandrel, under the conditions he describes, would have been as readily accomplished, whatever that mandrel might have been; and I fear that Dr. Edmunds' desire to find a screw to replace any other in apparatus for ornamental turning at all ironmongers, will hardly be realised, under any circumstances, until such apparatus is as universally required, as such ordinary objects as gasfittings or other ironmongery.

64, Charing-cross. **John J. Holtzapffel.**

SCREW-THREADS.

[19875.]—IN my second paragraph, on p. 55, it would have been more correct to say that Whitworth's thread is rounded off till the whole depth is $\frac{2}{3}$ of the theoretical *depth*—not *pitch*. In Holtzapffel's book, note on p. 670, Vol. II., quoting from Whitworth, there is this passage—viz., "Making this deduction, the angle of 55° gives for the actual depth rather more than 3-5th, and less than $\frac{2}{3}$ of the pitch."

Now, 3-5 = 9-15, and $\frac{2}{3}$ = 10-15, so the real depth lies somewhere between 9 and 10-15th of the pitch of the screw, and if we take it as half-way between those, it would be 19-30th of the pitch. If you draw a square and bisect one side, and from the point of bisection draw lines to the opposite corners, you will find those slanting lines to include an angle of 55° very nearly, say 53°.

In this case we have a right-angled triangle, whose sides, which include the right angle, are as 2 : 1. If the hypothenuse is double the short side, then we get 30″ as the acute angle, as in Fig. 2.

FIG. 1.

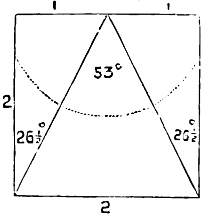


FIG. 2.

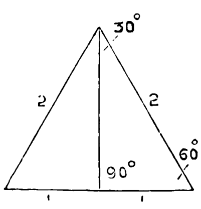

A mathematician would say thirty degrees is the angle whose natural *sine* is ·5. And 26° 34′, nearly, is the angle whose natural *tangent* is ·5, which is, say, 1° of arc different from the half of 55°.

I see I left off talking of "taps of other makers" when I had mentioned Clements's. Of Holtzapffel's, I only remark that I do not possess a single specimen, or even copy, though I have a set of seven pairs of his chasing-tools. I greatly prefer Whitworth's for holes in cast-iron, and for iron screws, and for machine tools and engines; but for small work connected with lathes, I think them too coarse, as, *e.g.*, $\frac{1}{4}$in. diameter, 20 threads to an inch, for the latter purpose would be better, 24, 25, 28, or even 32 to an inch, all of which sizes I have of Clements's threads. So, again, $\frac{3}{8}$in. diameter instead of 16 to an inch, might be 18, 20, or 25, as before, the last specially for leading screw of eccentric chuck.

I think Holtzapffel's threads are *in their proper place* only in such beautifully finished work as H. and Co. turn out, but that, on account of their great depth, they are quite out of place anywhere else. The time consumed in cutting such very deep threads, and the difficulty of keeping them truly upright, and the extra trouble in fitting, and hence the greater chance of not fitting accurately, and the fact of a non-fitting deep thread being ten times worse, from a practical point of view, than a fairly-fitting shallow one, most especially for slide-screws, make me entirely averse to the use of them myself, or to permitting their use in any but the very highest class of work, which alone can pay for their adoption. Of taps of "other makers," I think I may advise intending purchasers to *think twice*; but to send once and for all *for* Whitworth's *to* Whitworth's. As, in the first place, you get the genuine article, and in the second, I think I may say that the price is not so high as that of pretended copies.

J. K. P.

COMBINED OVAL AND ECCENTRIC CHUCK.

[19876.]—I WAS much interested in "F. W. G.'s" letter, No. 19833, giving an account of the way in which he combines the two chucks in one, though it seems to me that the removal of the arms may be attended by the risk that the nose of the chuck may be somewhat displaced from its true position when they are replaced.

It has, for some time, occurred to me that it would be possible to combine the two chucks by taking an eccentric-chuck and cutting in half the boss through which the leading screw passes; these two halves should then be mounted on a right and left-handed screw, so that they could be screwed clear away from contact with the leading-screw, and so allow perfect freedom to the slide.

The addition of the usual arms and ring would then make an efficient oval chuck of it, and there would be never anything to remove; the mere turning of the screw on which the halves of the boss are mounted, would suffice to change the chuck from one kind to another.

I should be glad to hear what "O. J. L." or other correspondents have to say about this proposal. **C. W. Bourne.**

LATHE AND LATHE-MAKING.

[19877.]—I THINK it would be more courteous in "J. K. P." if he would refrain from guessing at what he himself says he cannot understand (though the analogy between poetry and trigonometry is not very clear), as it may be just possible there are others to whom it does convey an idea. It does not appear to have occurred to him that there may be some value in showing what a thing theoretically *ought to be*, even though it cannot be exactly carried out in practice. The "nomenclature" to which he takes exception is certainly somewhat extraordinary, as the printer has expressed the fractions by sloping lines, which was not as I wrote them. I would also "mildly" suggest that it was not of the "shop" we were talking, but of certain *lathe-cut* screws used for ornamental turning, which are, or profess to be, always cut sharp "up," and not rounded off in the very useful but withal somewhat slovenly way adopted by Whitworth. No sensible amateur would buy an ornamental lathe with such a mandrel screw; indeed, I am at a loss to understand how such violations of the eternal fitness of things as threads of 9·45 per inch, *et id genus omne*, are tolerated for an instant anywhere except in the "shop," where I imagine it would never occur to anybody to ascertain what the pitch of a screw was.

I shall be very glad to do as Dr. Edmunds suggests; meanwhile I subjoin the differences in diameter, answering to a few angles as obtained by the aforesaid objectionable formula. D = diff. of diameter at top and bottom of thread, f = thread.

30° D = 3·732″ ÷ f
35° D = 3·172″ ÷ f
40° D = 2·747″ ÷ f
45° D = 2·414″ ÷ f
50° D = 2·144″ ÷ f
55° D = 1·921″ ÷ f
60° D = 1·730″ ÷ f

And if the angle = 53° 8′ 12″ we have D = 2 ÷ f, or the depth is equal to the pitch. Should there be any rounding off, this must, of course, be allowed for, and a slight allowance for unavoidable inequalities, or the male screw will not enter.

Scorpio.

CONTINUOUS BRAKES.

[19878.]—THE Continuous Brakes Bill, mentioned upon pages 562, 592, of last volume, was presented to the House of Lords by the Right Hon. Earl De-la-Warr on the 24th of February, and read a "first time." On Monday, March 20th, a large number of petitions were presented in its favour, and, after a short discussion, it was read a "second time" without a division. The Great Northern Railway Company has always opposed the use of automatic brakes, and consequently the Board of Trade conditions; therefore the chairman, Lord Colville, spoke against those brakes, and in support of his argument quoted "a recent accident in America alleged to have been occasioned by the automatic action of a brake." This statement was accepted as correct, as none of the noble lords present appeared prepared with a reply. It should, however, be clearly understood that *automatic action had nothing whatever to do with the accident.* The Spuyten Duyvil disaster (it was proved by the official inquiry), was caused by a tipsy passenger tampering with the brake, and pulling the safety-cord, thus stopping the train; the line was *not* worked upon the block system, and the guard or brakesmen neglected to perform the very important duty of going back and protecting his train by hand-signals. Safety cords and efficient communication between passengers, drivers, and guards are very necessary, but, of course, may cause very serious delays and even danger if improperly used, and most certainly the control over the brake power should not be placed in the hands of passengers.

Lord Colville has directed special attention to this American accident; but it is a strange fact that upon his railway (the G. N. R.) the following regulation is in force: –

"The guard's communication cord must be attached to the lever of the brake of the engine, and not to the gong on the tender of those engines which are fitted with the vacuum-brake."

The Vacuum-Brake Company claim for the system "that it can be applied by guards or *passengers* by means of the communication-cord." This statement is also repeated in the *Railway Engineer*, March, 1880.

It will, therefore, be seen that passengers on the Great Northern Railway *have* the power to apply the vacuum-brake, and, although it is non-automatic, a "tipsy passenger" may pull the cord and stop the train, and thus risk a collision precisely similar to the one at Spuyten Duyvil.

In a very interesting article, which appeared in the ENGLISH MECHANIC, Vol. XXXIV., page 225, reference was made to a so-called conference held at Euston upon the continuous brake question. As only those engineers were invited to attend who were well known to be strongly in favour of the vacuum system, the result was of course a foregone conclusion. On the 16th inst. another private conference was held, consisting as before of the advocates of the vacuum system; but in addition Mr. Tennant, of the North Eastern Railway, was invited.

Representatives from the Midland, Great Western, and Lancashire and Yorkshire Railways advocated automatic vacuum brakes. Mr. Tennant spoke most strongly in favour of the Westinghouse brake now fitted to a very large portion of the North Eastern Company's rolling stock. The meeting at once became discordant, and when Mr. Moon, Mr. Webb, and others expressed an opinion against automatic action altogether, it was seen that there was no chance of any unanimous decision being arrived at. The brake question is one of very great importance, and to obtain a correct conclusion, it is essential that the subject should be fairly and clearly discussed.

A committee of impartial engineers could easily settle *which is the best brake*, but unfortunately the difficult part of the question is how to overcome the crotchets and interests of certain officials. This is well known in railway circles, as the following quotation from the *Railway Review* will show:—

"Some engineers in the employ of the companies have entered the field as inventors, if not as speculators, and they naturally use their influence to promote that invention in which they have a direct or indirect personal interest."

For many years it has been known that the chain-brake which was adopted by the London and North-Western was very unsatisfactory; the Board of Trade reports have constantly called attention to its defects; but in spite of public opinion, the stock was fitted with it; now, after some £70,000 has been spent upon it, we are informed that this brake is discarded, and that it is to be replaced by a "continuous brake," and a North-Western train has been fitted with a vacuum brake which appears to be known as the Webb-Gresham.

The directors of the North-Western having wasted such an enormous sum of money upon the Clark and Webb brake, will, I think, carefully consider the subject before they adopt a new and untried system, which it is stated does not fulfil the Board of Trade conditions.

To adopt an inefficient brake would be a very unfortunate step, as it would delay the settlement of the brake question, and in a few years' time the additional expense would have to be incurred of changing again. In my next letter, I hope to refer to the subject of automatic air, and automatic vacuum brakes. **Clement E. Stretton.**

Saxe-Coburg-street, Leicester.

SCREW-PROPELLERS.

[19879.]—CAPT. CURTIS'S letter, 19841, surprises me. An efficient scull-propeller must not be forked, and need not be flexible. There is very little analogy between a fish and a steamship. The former is entirely immersed, like a torpedo, the latter has a great deal of freeboard to keep it from entire immersion. The stream lines following a vessel are very different to those following the motion of a fish, and require a totally different treatment, as I pointed out in my former letter.

Then Capt. Curtis says you *cannot go astern with it!* Why not? A steamship is not a dingey, with a half-round hole in its stern for a scull to work in. A large steamship would be fitted with one or two propellers (sculls), say 30ft. long, from the outer end of the blade to the journals; the latter would be about 2ft. in diameter, and the blade about 5ft. wide, at its widest part. It would be made of steel or phosphor-bronze, and cellular. Such a propeller would be capable of stopping the ship suddenly with greater power than the screw, and of driving the ship astern without any difficulty.

25th March. **Thomas Moy.**

MR. BENNETT'S BATTERY.

[19880.]—SEEING several correspondents have failed in making this cell work to their satisfaction, it may be interesting to them (and others) to know that, in reply to a note from me, Mr. Bennett says: "Wrought or cast-iron turnings may be used indifferently in my battery; there is a variation, it is true, but too slight to be noticed in practical working."

He very kindly adds: "You are at perfect liberty to send this reply to the ENGLISH MECHANIC."

Birmingham. **John J. Gilbert, A.S.T.E.**

LEGAL REPLIES.

[19881.]—INCOME-TAX (46365).—I am inclined to think the surveyor is right, and that "J. W." must claim a return of what he has overpaid upon the proper forms; but I do not pretend to an accurate knowledge of this special subject.

LEGAL (46439).—In this case the gift to B. and C. vested at once, so that the death of C. before D. made no difference. Therefore, C.'s will operates to pass his share to E., and the fact that E. is the issue of an illegal marriage has nothing to do with the matter. A person can give his property where he likes, and E. can proceed against the executor under C.'s will for an administration of the estate, either in the high court or, if the property be below £500, in the county-court. The executor ought to have proved C.'s will and acted under it, and he has no excuse for his neglect, as the reason he gives is wholly erroneous.

MORTGAGE (46453).—Without seeing the deed of mortgage, and knowing more about the facts, I cannot be certain in this case. But presuming that the mortgagee had a proper power of sale, and has used it legally, the only course open to "M." is to sue the mortgagee for an account. This could be done in the county-court, and might cost £20; but if he is right, these costs would have to be paid by the mortgagee. But this is peculiarly a case upon which I cannot advise without seeing the papers, as until then I could not say whether it would be taken up by a solicitor at his own risk, as seems to be suggested.

LANDLORD AND TENANT (46480).—A weekly letting can only be determined by a week's notice to quit; or by the parties agreeing to waive that notice. In this case it seems that the tenant has simply gone away without notice, and therefore he remains legally liable. Possession of a key is only evidence from which a tenancy may be inferred; but it is not conclusive. Coupled with the want of notice, it would, however, support an action for rent against the tenant who has gone away. "Householder" can certainly sue for the rent as against the person who had paid before; and if he wants to determine the tenancy he should give notice to quit, upon the expiration of which he can sue for the value of the key, if it be not returned.

LEGAL (46188).—The only remedy Mr. Babbage has is to bring an action for damages against the owner or occupier of the foundry, on the ground that the chimney is now a nuisance; and he should ask in that action for an injunction ordering its removal. Presuming the facts to show that the smoke constitutes a legal nuisance, the only possible defence would be that the foundry had been on the present site for over twenty years, and so had acquired a right to be a nuisance to its neighbours by prescription. But that right would only apply, as far as I can judge, to the chimney when it was 50ft. away, and the bringing it as close as 15ft. would probably be a good ground of action; but, of course, all must depend upon the evidence.

Fred. Wetherfield, Solicitor.

2, Gresham Buildings, Guildhall.

DYNAMO-MACHINES.

[19882.]—I NOTE "Humble Bee" (letter 19822) recommends the study of the laws of magneto-electric induction to those who would construct apparatus in which the said laws are involved. Now *I* "don't want to be rude" either, but it strikes me he would do well to inquire a little more closely into them himself.

He says I am under the impression that the bobbins of the Brush armature are only able to contribute anything to the current during a quarter of the revolution, when they pass from one pole to another, and that this portion of revolution is the weakest part of the field; also that the strongest part of the field is between the field-magnet poles. This is all perfectly true. But is "Humble Bee" aware that the currents induced in the bobbins are not necessarily most powerful when they are under the most powerful induction? It is a well-known law that currents are only induced in wires when the inducing-power either increases or decreases; consequently, no current would be induced in a bobbin when it was passing between two poles, even if they lifted a ton weight each, unless the power of the induction was made to increase or decrease by having the polar faces slightly sloped in such manner that the bobbins would gradually approach or remove from the poles as they moved round. In the Brush machine the bobbins practically remain at the same distance from the inducing-poles all the while they are between them. So the strongest part of the field is wasted.

I asserted, in my last letter, that I had designed a generator which was free from several of the main defects of other machines. The bobbins on my armature either approach or recede from the faces of the inducing-poles during the entire revolution; the armature is in the best possible position for utilising their inductive power. The heating of the armature through reversions of magnetism in the iron is entirely done away with. In all the annular armature machines of any note the iron in the armature takes little or no part in the generation of currents, whereby considerable power is lost. This is made evident by taking the iron core out of an induction-coil and interrupting the current by an arrangement worked by hand, when the coil will be found to have lost some little power.

In my machine the iron of the armature is so disposed as to be very powerfully magnetised, and it is through this chiefly that the current is produced. In the Gramme and Brush armatures the iron is too thin to help the current to any considerable amount, and, if made thicker, it would act deleteriously upon it.

My armature A (Figs. 1 and 2) consists of two

FIG. 1

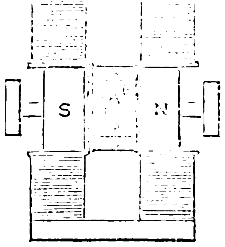

FIG. 2.

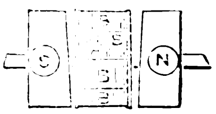


brass wheels, fitted upon a steel shaft, and carrying between their rims six or eight bobbins, B, of insulated wire, each with a round core of well annealed soft iron in its centre. Practically, they are so many small straight electro-magnets. This revolves between two field-magnets with opposite poles, N and S, on opposite sides of armature, the latter being placed as shown in Fig. 1. The ends of the iron cores of the armature bobbins project slightly through holes in the rims of the brass wheels, and it will be evident, on turning to Fig. 1, that these cores will be powerfully magnetised, as they are in the most concentrated field possible. The poles S and N are circular, and of same diameter as the armature, so that every part of the latter is under induction in every part of the revolution. Fig. 2 shows how poles are sloped so that each bobbin continually approaches till it reaches the lowest part of revolution; then, as the motion continues, it ascends and recedes till it reaches the highest. Thus, the power of the induction continually varies.

I now come to the point in which this machine differs from all others. It will be seen, on looking at Fig. 1, that the magnetism in the armature will never change during the entire revolution. All the poles of the armature cores next the north pole of field-magnets will become south by induction, and, as they never leave the north pole, but keep revolving before it, they never change their magnetism. In all other machines that I have heard of the poles in the armature must change twice every revolution, and, when it is rapidly rotated, the forced reversions produce much heat, injurious to the covering of the wire, and wasteful of power. Each bobbin is connected only with the diametrically opposite one, as in the Brush machine, and the commutator resembles the Brush, in having a separate pair of segments for each pair of bobbins; but it has no "insulators," as they would be quite useless. I fear I have taken up too much space already, or I would have sent a diagram of commutator, showing how bobbins were connected.

Conrad.

CHEAP DARK-SLIDES.

[19883.]—With regard to Mr. Fennessy's objection to the non-opacity of the shutters of the dark-slides described by me, I beg to inform him I have not experienced the difficulty he mentions.

I find that the application of one coat of Bates' black varnish effectually renders the shutter light-tight. **J. B. Stephen.**

Screw-Drivers. — Erratum.— A line was omitted in the print of Sir Edmund Beckett's letter about a screw-driver improvement last week. The second paragraph ought to have begun thus:— "All that is wanted is a short tube big enough to inclose the screwhead somewhat [loosely, and the screw-driver itself somewhat] tightly, but only spring-tight," &c.

REPLIES TO QUERIES.

**** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45516.] — **Hand-Thresher.** — I hope that "Strathtay" will discover that the sketch has been placed upside-down by some mistake. I might also mention that the whole frame should be closed with five-eighths lining.—Was-heil.

[45687.]—**Throttle-Valve.**—To "Sunlight."—I did study your proposed circular throttle-valve, and felt satisfied that, if anything like a fit, it would be very liable to bind in the box. I advocated the use of one part cast iron, because brass on brass, especially when hot, has a tendency to stick, and not to work kindly together. I knew very well where the spindles would be placed on a large throttle-valve, but objected to your using the expression "spindles placed upon the ends of the oval" (see page 617), seeing that said axis goes angularly through the centre. When proposing the use of a wood chuck, I was addressing the model-maker, not alluding to large work; and, as to the drilling of the hole of square section, I ask any of "ours" to refer to said page 617.—J. J. A., Liverpool.

[45766.]—**Watch Fusee Chain (U.Q.)**—"Bazil Amo" will probably find what he wants on page 619, No. 881 of this paper, in answer to query 46027. Arthur Frogham's is best as far as it goes; the others give the remaining information asked for.—C. M. R.

[45864.]—**Universal Joints in Shafting.**—I am sorry to see that one part of my query was not clearly stated. I am about to put down a line of shafting on a very steep convex incline to drive a threshing-machine, at a distance of 270ft. from the water-wheel (a chain being previously used for driving it). Four Hooke's universal joints will be used on the different inclines at angles of 15° each. I am under the impression that it would take considerably more power to drive the shafting with two universal joints at angles of 40°. Would "J. T. M." kindly give a fuller description or a sketch of the "cup-and-ball" universal joint?—Ignoramus.

[45962.]—**To Mr. Allen (U.Q.)**—"M.I.C.E." has misunderstood this query. I believe the transparencies inquired about were carbon prints mounted on glass; such, at any rate, were the very beautiful transparencies shown at several British and French exhibitions.—W. J. Bashford.

[45964.]—**Glass Transparencies (U.Q.)**—A few years ago I used to amuse myself during the winter evenings in making glass transparencies in the following way, with very satisfactory results: Sensitize an ordinary collodion plate, and, after draining well in a non-actinic light, place it, face downwards, on the face of negative in an ordinary printing-frame, putting four small pieces of thin cardboard at corners, to prevent contact with the face of negative. Now all is ready for exposure. Don't place the printing-frame too near the light. I used a paraffin-lamp, with a medium-sized wick. Expose from half a minute to two minutes, as practice alone will show, and then develop, &c., in the ordinary way by a non-actinic light. I really forget whether I fixed the pictures or not; but this may be tried with a weak fixer. Then dry and varnish the plate, and you have a transparency which, I think, will meet with your approval.—W. H. Scriven.

[46018.]—**Turbine for Low Fall.**—If "A. L." will refer to Templeton's "Workshop Companion" he will find rules in it for calculating the power of turbines, and if he (or any other reader interested in turbines) intends visiting the Royal Agricultural Show this summer and advertises his address, I will send him my address, and will be most happy to show him two turbines at work and one idle, with a fall varying from 2ft. to 3ft. 6in. When the water is clear the wheel can be seen revolving round.—Stratheden.

[46077.] — **Enamel Paint.** — This is either ordinary paint worked up with varnish, or it is the cheap enamel used for covering ironware. In neither case is it proof against "acids."—J. T. M.

[46092.]—**Gas from Oils, Fat, &c.**—The gas is made in the usual way by distilling the substances and securing the hydrocarbon vapours. It would require specially-constructed plant, and is out of the question in this country where coal is so cheap compared to oils, &c. The only oils that would be used for the process are mineral oils, and gasoline is about the cheapest and best, all things considered. The air-gas will then cost about 6s. per 1,000 cubic feet.—S. Mayer.

[46093.]—**Gun-barrel Staining.**—The art of staining gun-barrels is very simple when you have had plenty of practice; but those who try for the first time must expect to make a mess of it. However, there are several recipes in back volumes; but, of course, you have not them. Dissolve quarter ounce of sulphate of copper in some rain-water (you will want nearly a pint altogether), add ¾oz. of sweet spirits of nitre, ¾oz. spirits of wine, 1oz. tincture of steel (ferric perchloride), and ½oz. of strong nitric acid. That will make a pint, say, and is enough for 30 or 40 barrels. Clean the barrel thoroughly (a good plan is to cover with wet lime and wipe off when dry); then, with a sponge and a stick, coat the barrel with the mixture, and put it in a warm place (80° to 90°) for twelve hours. Then scratch-brush, or go over with wire card, and let cool. Repeat this performance twice, barring the scratching, and only leave about six hours. Then immerse in boiling water till they are quite hot, and wire card again; repeat the coating and immersion as often as necessary, and when done wire card and oil. It will be understood this is a process of "rusting," and everything depends on the skill of the workman. A simpler process is to coat several times with a paste of butter of antimony and olive-oil.—Nun. Dor.

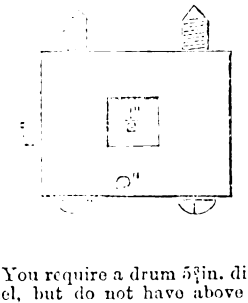
[46101.] — **Emigrants' Outfit.**—Clothes and tools are about the only things necessary to take out—a complete waterproof suit of oil-skin being a principal thing.—Ontario.

[46120.]—**Hand-Power Tricycle.**—The best way would be to send for the lists of the makers—*e.g.*, Bayliss, Thomas, and Co., Coventry, who make a hand-lever machine, and the Manchester Tricycle Co., Exchange Arcade, Manchester, who make a tricycle to be worked by hands only, using a crank-axle just in front of the rider.—B. U. B. T.

[46127.]—**Snails.**—I do not know that snails are of any great value medicinally; but they are considered a luxury by some—perhaps you would think so, too, if you were not aware of the nature of the dish. In several countries on the Continent snails are reared as articles of food, and I believe that, when boiled in milk, they are thought to be beneficial in lung-diseases. The cultivated specimens of Helix pomatia fed in the gardens of the merchants are very large, and fetch tolerably high prices; but, on the shores of the Mediterranean, what I may term the wild snails are considered to be excellent food. They are boiled in the shells, just as we cook "winkles."—Nun. Dor.

[46135.]—**Heinrich's Dynamo.**—I think I can answer this question. The machine is being experimented with on the Continent, and will probably be in full work when some of those now at the Palace are forgotten.—Nun. Dor.

[46148.]—**Fret-Saw and Lathe.**—"J." had better get four pieces of hard, dry wood, nicely squared up, and holes carefully put through for rods to work in. It is cheaper and quieter, and wants no oil; black lead only required; bearings are not an improvement; the upright can be cut off as high as you please; 3in. from table is enough. You require a drum 5¾in. diam. for your 29in. wheel, but do not have above a ¾in. throw for your under crank; short and quick stroke is best. I use steel staples, but have found the dust licks up the oil, and wood answers just as well for guides to the top and bottom rods; that is why I now recommend hard wood.—Wm. Hosken, Penryn.



[46210.]—**Wheatstone Bridge.**—I do not see why "Number and Angle" has selected from ½ohm. to 220ohms. for his coils; but perhaps he has some particular reason for these limits which he has not explained. He does not mention that he has prepared any coils for the two square branches of the "bridge," and I do not quite see what he can have done. Perhaps the simplest plan of explaining the matter may be to give a description of a set of coils I have been engaged on lately, and have just completed. They are arranged in three rows in the box thus:—

C { 500 – 100 – 20 – 10 – 10 – 20 – 100 – 500 A
D { ·1 – ·2 – ·3 – ·4 – 1 – 2 – 3 – 4 }
E 400 – 300 – 200 – 100 – 40 – 30 – 20 – 10 }
F B

The upper row forms the bridge; the plugs may be pulled out to put two ten ohms., or two twenties, two hundreds, or two five hundreds in circuit, according to the resistance to be measured; or the 100 plug may be pulled out on one side, and, say, the 10 plug on the other, when any measurements will be multiplied or divided by ten, according to the side from which the hundred plug is removed. The two lower rows form the third branch of the bridge, the resistance to be measured making the fourth. The letters A and B are the binding-screws for the resistance; C and D are for the battery, and E and F are for the galvanometer. In front of the three rows of plugs is placed the contact-maker, which is constructed as shown in Sprague's book, so as to first make the battery contact, and then the galvanometer ditto. The connections are as follows (I have not shown them, as if I had done so it would have required a block, which I wish to avoid if possible). Lead wire from between the two 10-ohm coils to E, also from between the 500 and ·1 ohm to C, the other 500 to A, and a branch wire from here to the battery contact-maker, from whence it goes to D. Lastly, connect the 400 coil to B, and lead branch wire to galvanometer contact-maker, from which it is led to F. It will be understood that the coils are inside the box, and the two ends of each one are connected to pieces of brass above, which are short-circuited by the brass plugs that are fitted in, and any coil will be thrown into the circuit by the removal of the plug above it. The galvanometer required for measuring resistances may be simple; there is no particular good in having a lot of different wires on the bobbins. Mine has about 150 turns of No. 18 copper wire, and I can read to the tenth of an ohm when measuring two or three hundred. But if making another, I should put finer wire, say, 400 or 500 turns of about 24 B.W.G. The great thing is to get the needles to move with the least possible current. They must, therefore, be as nearly astatic as possible, and be suspended by a fine silk fibre. I may mention that, if properly adjusted, they should swing very slowly, not more than five swings a minute, and it is important in using such an instrument to empty the iron and steel out of your pockets, or the needles will always move when you do. I find even my watch will deflect pointer two or three degrees if brought within a foot or so. It will be noted that such an instrument is simply a galvanoscope, and not, properly speaking, a galvanometer; that is, it simply shows that there is a current, but only gives a very general idea of its strength; when it is required to do this quite a different instrument must be used. I have made such a one on the tangent (and sine) principle, that I shall be pleased to send description and drawing of, if desired; it will measure with accuracy any current from about one thousandth of an ampère up to twenty-five to thirty ampères.—R. P.

[46320.]—**Motor.**—In reply to "Sunlight," I seek information as to the form of motor I could procure to work the machine. The machine is a model I wish to show at work in various places, and would not require it to work more than an hour at a time. As a regulated speed is desired, the motor must be under control.—Poor Peter.

[46344.]—**Locomotive Matters.**—There are two peculiarities about the Belpaire firebox. They are not always met simultaneously, as on the annexed sketch. The first is the grate: my readers are well aware that for a many years coke alone was burnt in locomotives; when coal was first used many systems of grates were devised to abate the smoke. English coal was imported in France for railway locomotives from Cardiff, Newcastle, &c. But it was found more desirable and more economical to use French and Belgian coals. But these coals are still dear, especially if they are to be used in lumps; the cheapest sort, and by far the most considerable sort, is the "menu," or slack. This slack is not free from earthy matters, and in its divided state it will pass through the grate in no time. This is a waste. Moreover, it is not advisable to burn it in a deep fireplace. The layer of coals must be thin and uniform, the air-spaces very narrow, not more than 9 millimeters; the air is admitted at the level of this layer by openings in the fire-door; this opening can be closed at will. The bars are cast together, in parts, or, when of wrought-iron, so riveted. A drop apparatus is

FIG. 1.

FIG. 3 No. 2. 1877.

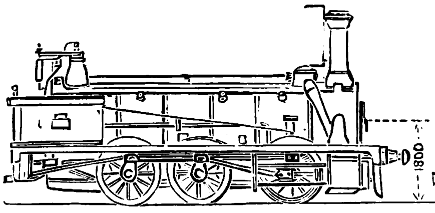

FIG. 4. No. 1. 1858.

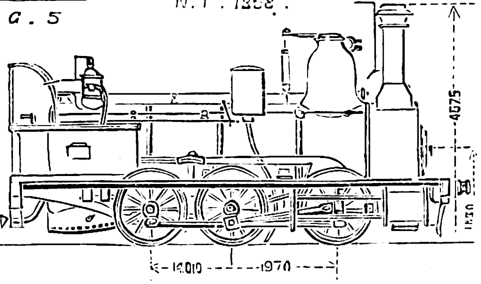

provided to throw the fire. The firebox cannot naturally be made high, and it will be seen at once that the grate can be placed over the hind axles, this is a great advantage, favouring a good repartition of the weight. The length of the firebox is often 7ft. The second particularity is a mode of staying the crown-plate of the firebox. It is an extension of that adopted for the vertical side of the firebox. The origin of this new system of staying has been contested. M. Belpaire, however, may not have known that it was applied first by Crampton, on one of his celebrated engines. The late Mr. Bouch, engineer of the Stockton and Darlington Railway, also used a very similar staying of the crown-plate. From the sketch it will be seen that both crown-plates, outside and inside, are flat; both are strengthened by long steel, or wrought-iron screwed stays, a little over 1in. in diameter, pitched 4in. apart. They are hollow, but the end on the outer case is closed. The hollow through the stays is ¼in. in diameter. If one broke the steam or water would rush immediately into the firebox, thereby signalling the danger. These fireboxes must have their corners struck with a great radius. The unavoidable flat parts are easily strengthened by palm-stays or screw-stays, as shown on sketch. The latter sort is preferable for two reasons: a hole can be also drilled through them, or even managed when rolling the stays. The other reason is that the first sort of stays cannot be easily repaired, give no signs of failure, and, if not riveted, may work loose. The advantages of this firebox are: 1. Enlargement of steam-room. 2. The screw-stays do not oppose the rapid generation of steam that takes place there. 3. It is cheaper, and in the event of a failure, soon made right again. 4. The crown-plate is easily cleaned and examined through the little openings, A, A, A. In this country, the direct staying of the crown-plate to the outer casing has been also adopted, but in keeping the old form of firebox top this is not commendable. Keeping the old form of outer firebox requires a particular shape of crown-plate, for we know that the stays have to be normal to both plates. This condition is realised in the case of concentric cylindrical surface; but, should this become possible in locomotives, staying does not seem necessay; but it is impossible, owing to the diminution it will inevitably cause in the heating-surface. Curved surfaces, but not circular ones, are resorted to, and, for the purpose of keeping the stays normal to them, they are altered a little in shape at the place where these stays are screwed, and in such a manner as to secure the desired result. This is the practice on the L. B. and S. C. I do not think it is simpler than Belpaire's method. All fireboxes with direct screw-staying of the crown-plate have a disadvantage. The stays must not be too near the tube-plate: otherwise, on lighting the fire, the expansion of the tube-plate will often cause the plates and stays to become leaky. The best means to avoid this is to adopt the sling stays shown at that part on the sketch. Belpaire's firebox is adopted in name on the Chemins de fer du Nord, de l'Est, de Lyon, on all Belgian railways, by Borsig, of Berlin, and some other Continental railways. Bourbonnais type: The Bourbonnais type owes its name to the fact that, when first created, it was destined more particularly to work on some of the railway lines that are found in that part of France formerly called Bourbonnais. The first engines of this type were built in 1858 by Cail and Decrosne, from the designs of M. Houël, the principal engineer of that firm. They first worked on the Lyons and Roanne section; but, when the Paris, Lyons, and Mediterranean Railway received its present extension, through the amalgamation of different lines lying in the south-east of France, the system under our consideration was adopted throughout all parts of the *réseau*. The Bourbonnais type is an outgrowth of the long boiler type, applied to meet the requirements of heavy traffic. It is an outside cylinder engine, with inside valve-gear. Both firebox and cylinders are overhanging; but, abroad, this is not considered a fault when it is a question, as in the present case, to draw heavy trains at a slow speed. The P. L. M. Company possess to-day over 900 engines of this sort. They were built during the last twenty-five years by different makers, with slight modifications. I have given on the annexed sketches the diagrams of the first engine and of the most recent, to my knowledge. It must be remarked, by the bye, that the Bourbonnais type is fast being adopted by other railway companies. You will find it on the Alta Italia Railway Company, for instance. I have in my possession the auto-lithographic working drawings of some locomotives by various French companies, exactly similar to the Bourbonnais type, as far as regards mechanism. The engine No. 1 was considered as the most powerful six-wheeled engine for goods traffic that could be adopted safely on the normal gauge. Time, however, showed that this opinion was not strictly true. The engine No. 2 must be somewhat more powerful than No. 1. The latter was used on inclines of 18 to 20mm. per mètre (about 1 in 50). Here are the following changes occurred in the construction of these engines during the last 25 years. The services of these engines are now required for the passenger traffic. On inclines 1 / 200 they can draw 400 tons (goods) at a speed of 15·6 miles an hour, or 235 tons (passengers) at 28 miles. The pumps are now replaced by a single but powerful injector. It is, however, difficult to understand why two are not used. This injector (No. 9) can deliver over 25½ gallons a minute. All recent engines have a capacious dome against the smokebox. This dome carries the safety-valves, which were before on the firebox. There are, on each engine, a large dry sandbox of a peculiar construction, and a weather-board. The wheels are wholly made of wrought Iron, and with spokes, oval in section. The engines are fitted with Lechatellier counter-pressure brakes. In both old and recent engines there is a peculiar arrangement for the springs of the trailing-wheels. It was difficult to find room for them to be disposed in the same way as the other two pairs. The nearness of the fire-box prevented the engineer from finding the place necessary to give them the proper span. They were replaced by the kind of double spring of shorter span shown in one of the sketches. It is to be remarked that such engines cannot have their frames braced properly from the same cause; however, the cylinders are fastened to these frames, and secured together in a manner worth imitating. I should be glad to describe it here, but I am afraid to trespass on valuable space, as my description is already too lengthy. The builders of these 900 locomotives rank amongst the first on the Continent, and I give their names, as it may interest some readers: Cail and Cie (Paris and Oullins-les-Lyon); A. Kœchlin, Mühlhausen; Claparède, St. Denis, near Paris; Creusôt Works (Saône-et-Loire); Ateliers de Fives Lille (Nord); Ateliers de la Compagnie, P.L.M., Paris. The following dimensions are metric, of course, but I give the nearest English equivalent for the modern engine.

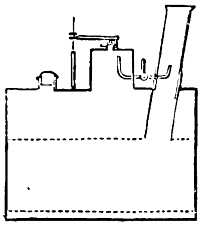
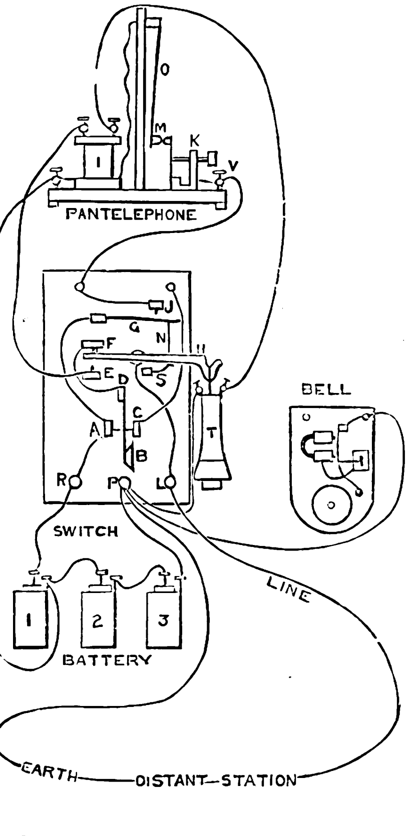
Kpd'l / D.—ED. GOBERT, B.Sc., Nottingham.

[46349.]—**Model Steamboat.**—The annexed sketch is the form of boiler required, the dotted lines showing section of firebox and uptake. It should be made of copper (a piece of 12in. sheet is most suitable) riveted, and of the following dimensions:—Length, 9in.; depth, 6½in., and 5½in. wide; diameter of firebox, 4¼in.; of uptake, 1¼in.; steamchest (which must be fixed with the flange inside shell of boiler), height, 2¼in.; diameter, 2in. (See below.) Firebars, 3in. wide, of ⅛in. iron wire, and long enough to reach to uptake,



where a bridge must be formed to within 1½in. of the crown. Steam-blast to be fixed as shown, with a nozzle just big enough to stick a pin into. A safety-valve is indispensable. A piece of tin or sheet-iron must be fitted into end of flue, and stopped with white-lead. With charcoal and small coal mixed, you can get a splendid fire and plenty of steam. A smaller boiler is utterly useless for a boat of such proportions. Firebox must be fixed ¼in. above the bottom of boiler.—J. H. G.

[46353.] — **Telephone Transmitter and Switch.**—I have found the pantelephone a good transmitter when combined with an induction coil, not without. The hanging plate I have made of pasteboard, also of thin wood, with like results, but have found the best effects when the contacts were of carbon only. I send a rough sketch of the pantelephone I made, showing the induction coil; also a sketch of a very useful switch suitable for



working the four instruments required in successful telephony—viz., the telephone, microphone, bell, and battery. This switch will be found useful to many of your readers, judging from the numerous inquiries on such matters. I have endeavoured to represent all connections, "make and break," as plainly as possible, so that but little description is required. I will first explain the way these instruments are brought into action, and in doing so will add the needful description. To call attention at the distant station, where it is assumed the same kind of instruments are in use, press the button B on switch for a second or two; this breaks contact with C, and makes contact with A. The current now flows from the battery, cell No. 1, through A to D, on to F, then along lever H to its centre, and down to post L, thence to line, and on to distant station, where it rings a bell; then to earth, and back again to central post P on switch, then to cell No. 3, and so completes the circuit. The "call" will be answered by the home bell ringing, produced by the same operation of pressing the button B at the distant station. This sends a current into the line to the home station, which, entering the switch at L, passes upwards to the lever H, along this to F, then to D and C, and upwards to one of the top parts, then out to bell, which it rings in passing, and on to centre post P, and back through earth to distant station, and so again the round is completed. Now remove telephone T from the hook H; the spring S at once lifts up this lever, and through the insulated connection (a silk thread), N, allows the spring G to make contact with J. Contact is also at the same time made by the lever with E, and broken at F. This operation brings the microphone or pantelephone into action. The current now flows from No. 1 cell only, this being sufficient to work the local circuit through the microphone. Its course is through A G J to pantelephone, which it enters at V, then passing by K through the loose carbons M to O; up this it passes by a wire, then down on the other side to the induction coil I, where it flows through the primary wire and back to the same cell No. 1, as shown. The secondary wire terminates in two binding posts shown on the top of the coil. This wire furnishes the current necessary to work the telephones. It starts, say, from the left-hand post and passes to E on switch, then along lever H, now in contact with E, and down to post L, thence through line to distant station, and through its telephone to earth, then back again it hastens to centre post P on home switch, and on through telephone to induction coil, whence it started. I may add that the microphone bell and switch are best combined in one instrument, though I have shown them separately the better to illustrate the action of each.—John C. Frank.

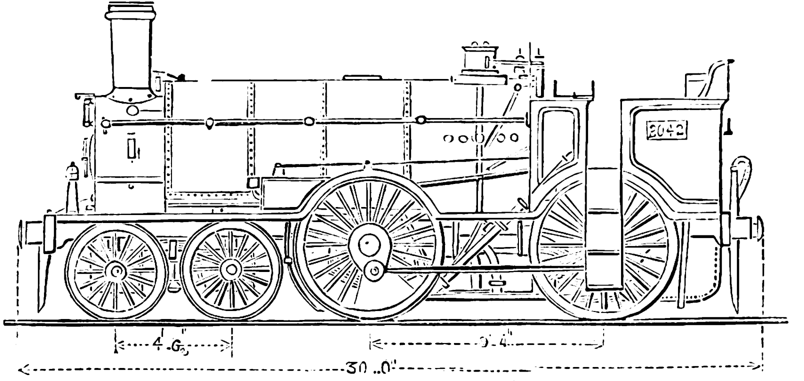
[46373.]—**L.S.W.R. New Coupled 6ft. 6in. Bogie Engines.**—There are twelve engines of this class; the numbers are 136 to 147 inclusive. The reason the numbers are so low is that the new engines have the numbers on them of old engines which have been broken up.—Clyde.

[46376.]—**Weight of "Grosvenor."**—The distribution of weight on the "Grosvenor" is as follows:—

	tons.	cwt.
On the leading-wheels	12	8
,, driving-wheels	15	8
,, trailing-wheels	9	4
Total weight	37	0
On the terriers:—		
On the leading-wheels	8	8
,, driving-wheels	8	12
,, trailing-wheels	8	6
Total weight	25	6

I don't know the weight of the "Grosvenor's" tender, but the wheel-base is—From centre of leading-wheel to centre of middle wheels, 6ft.; from centre of middle wheels to centre of trailers, 6ft.—Spike.

[46395.]—**G. W. R. Engines.**—In reply to "Stentor," I send sketch and chief dimensions of

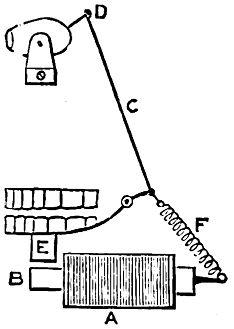


the 2042 class of tank-engines. The engines were built in 1867 by the Vulcan Foundry Co., Warrington, from the designs of Mr. T. Pearson, for the Bristol and Exeter Railway Co. A smaller class of the same type was turned out in 1862 by Bayer, Peacock, and Co.; and a larger type, represented by 2051, came, in 1873, from the Avonside Engine Co., Bristol. No. 2042 was No. 69 of the old B.E.R. Co. These engines have screw reversing gear, and they are fitted with the Saunders ejector for the purpose of creating a vacuum to work the brake on the carriages, but the engine is only fitted with the ordinary hand-brake, with wood blocks. The chief dimensions are as follows:—

	ft.	in.	
Cylinders	17in. × 24in.		
Coupled wheels	5	6	diam.
Bogie ,, ...	3	6	,,
Wheel base coupled	9	4	
,, bogie	4	6½	
Total wheel-base	19	8	
Length over buffers	30	0	
Length of saddle-tank	10	0	
Firebox (length)..........	4	4	
,, (breadth)	5	0	
Depth from crown to bars..	4	8	
Number of tubes	198		
Diam. inside	1¾in.		
Length	10ft. 3in.		

—Clyde.

[46380.]—**Electric Human Skull.**—I inclose sketch how to arrange the electrical part, which I



suppose you know something about. If not, take it to a friend or instrument-maker. A is an electro-magnet; B, pole of ditto: E, armature; F, spring for tension; C, lever for working the eyes; D, joint. A current being passed through A, B will attract E, and lever C moves eyes. If you want the teeth to chattter, place a contact breaker at D.—George Tolman.

[46386.] — **Cold - Air Engine.**—To "Sunlight."—I could not say if you would infringe or not, unless I saw the plans of the proposed motor. The chief cold-air patent is that of Giffard, which is considered a fine invention. But I have no practical experience of it, therefore could only give you a theoretical opinion that it is complicated with stuffing-boxes, and other parts not advisable in a motor of this class. As to a hot-air engine, that is another matter altogether. See my remarks on page 622 on the subject. But as far as I have gone in practice, I may tell you that the hot-air engine, in my opinion, is a far more reliable motor, if viewed from the point of actual use, than the cold-air one, and therefore I should not advise you to trouble yourself with latter.—Sunlight.

[46387.]—**Boiler.**—If an externally-fired one would suit you, and it is easiest arranged to burn coal, the size might be, say, 2ft. 3in. or 2ft. 6in. long, and 8in. to 9in. diam. If set in masonry, the grate should be 9in. by 9in. long, with a flash flue the length of the boiler, so that one-half its diameter is utilised as heating surface.—Sunlight.

[46390.] — **Turning Calender Rolls.** — I presume these rolls, or bowls, as they are sometimes designated, are constructed of paper which has undergone hydraulic pressure. Having an idea that these tools are numerous, and some of them kept secret, it would be more satisfactory to me, and also to "G. H.," to advertise his address. —Pattern Maker.

[46396.]—**To "Aldebaran."**—There are not only more lenses in a terrestrial than in a celestial eyepiece, but the principle is altogether different. In the former an inverted image of the object viewed is thrown directly in front of the first lens of the eyepiece (A, Fig. 1). This image, being considerably within the focus of the lens, causes the emergent rays to be much scattered, and, as will be seen by the sketch, a great portion of them to be wasted

FIG. 1.

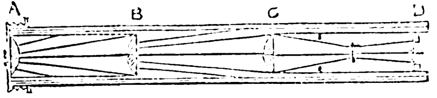


FIG. 2.

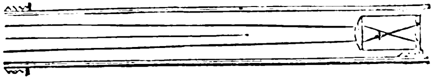

(a further loss of light being also caused by reflection from so many surfaces). The rays, after passing through the lens B, are more collected, but still divergent, and it is only when they have been again bent by C that they converge to a focus between C and D, and it is this focus or re-inverted image that, magnified by the eye-lens D, forms the field of view. The lenses B and C are not essential to the formation of an erect image, but are found necessary to correct the spherical aberration which would otherwise result. The magnifying power obtainable by an eyepiece of this description may be increased to an almost unlimited extent by separating the two pairs of lenses; but as such increase of power must always be accompanied by an actual loss of light, it is found preferable, for astronomical purposes, to adopt a modification of the pair next the eye (Fig. 2) known as the negative, or Huyghenian eyepiece, in which the cone of rays from the object-glass is bent to a focus midway between the two, and magnified as before by the eye-lens. An image viewed in this manner is, of course, inverted, but for celestial objects this is rather an advantage, because celestial scenery is usually depicted as it is seen in an inverting telescope.—Aldebaran.

[46397.]—**Slide-Valve.**—"To Sunlight."—The two slides are, next the cylinder itself the main slide, and on the back of that, the second or expansion valve. The main-valve, in this case, is not of the usual shape, but is more like a flat plate of some little thickness. In this thickness is cast through two ports or passages for the steam, and a recess only for the exhaust port; on the back of this main-valve is the expansion one, and it is a plate likewise, but thinner, and with ports cast through to match those in the main-valve. These two parts, sliding one on the other, bring the ports into position, so that at the commencement of the stroke the two ports come fair one with the other over the port that should admit steam to the cylinder. But as the main-valve moves downwards, let us suppose the expansion one is moving upwards, so that the port is closed doubly as quickly as it would be if but one valve was used; therefore by altering the relative position of the expansion-valve, the cut-off is easily caused to take place at the early part of the stroke or not, as the required grade of expansion may be.—Sunlight.

[46400.]—**Winter's Plate Electrical Machine—Coil.**—In reply to this I beg to state that I divided my coil into the three parts for experimental purposes, so that I may examine the effect of the primary on the different parts of the coil, which I can do by means of binding-screws on the different divisions (not shown in Fig.) In the coil I am binding I shall have not less than 150 of these vertical divisions, but of paraffined paper instead of ebonite. I believe you can get better insulation this way, and less liable to injury of coil by striking into the primary. I do not know a good winding apparatus. Mine was a very primitive one, consisting of a solid base and two uprights, to take the core and primary (the core projecting beyond the primary coil). A handle fixed to the core turned it round. I found I could soon wind it on after a little practice with the first two or three layers.—Thos. N. Andrews, Plymouth.

[46405.]—**Stains on Dry-Plate Negatives.**—To remove yellow stains, try soaking the plate in alum, 1oz.; citric acid, 2oz.; water, 1 pint. I doubt whether you will ever bring back your negatives to their original printing quality; you can try the following:—Remove the varnish from the plates and then give them a bath of hypo; now wash well and re-intensify as follows:—Place the negative in a solution of bichloride of mercury till it becomes white, well wash and immerse in water, 1oz.; ammonia, three drops. Leave the plate in the latter solution till it has become almost black, then well wash again. Do not omit to wash well after the mercury solution, or the plate will be spoilt.—H. G. M. Conybeare.

[46406.]—**Rainband Spectroscopy.**—Full particulars of the spectroscope employed for this purpose will be found in the "Plea for the Rainband," which has appeared in *Symons's Meteorological Magazine* (Stanford, Charing-cross), *The Observatory* (Taylor and Francis, Red Lion-court, Fleet-street), and has been noticed in your journal, and a reprint of which, in a pamphlet form can be had of Mr. John Browning, 63, Strand.—J. R. C.

[46415.]—**N.L. Tank Engines.**—I send dimensions of the outside cylinder tank engines, No. 1 class, the first of which came out in 1868. Cylinders, 17 by 24; driving-wheels, 5ft. 6in.; dia. of bogie-wheels, 2ft. 9in.; dia. of boiler (inside), 4ft. 1in.; 200 tubes, 1¾in. dia., ¾in. clearance; bogie-wheels, centre to centre, 5ft. 8in. The bogie-wheels are capable of lateral transverse movement 2in. each way. The boiler-pressure = 160lb; heating surface, 1,015 square feet. Weight in working order:—

	Tons.	cwts.
On bogie-wheels	14	14½
,, driving ,, ...	14	5
,, trailing ,, ...	14	12½
Total	43	12

When the engines came out, the average consumption of coal was 30·28lb. per mile with twelve coaches. The trains may be heavier now. I may add that the dimensions are those of the No. 1 class; I do not know whether they apply to the 70 class, which are of a later date. A sketch of these engines was given in one of the earlier volumes (I believe Vol. X.) I do not know dimensions of the inside cylinder engines; I have only seen them from a distance. Are they not painted black, and numbered from 101—110?—Meteor.

[46419.]—**Telescope.**—To "Aldebaran.—A telescope of the class described by "Wykehamist" ought to make a most excellent astronomical instrument, and as the process of conversion is exceedingly simple, it will be quite worth his while to do so. I should, however, advise him not to interfere with it as a day telescope, but rather to fit to it an additional tube for night work (as shown in Fig. 2, 46396), or if he wished first to test its capabilities as a night glass, he might unscrew the two pairs of lenses from the eye-tube, and replace the one next the eye by a celestial eyepiece such as described on page 608 of last volume.—Aldebaran.

[46424.]—**Circular Saw.**—It has most undoubtedly got buckled. Send it to a saw-fettler's; he will hammer it for you, and in future do not let it run hot, but give your teeth proper clearance, and be careful when filing and setting, and, above all, see that your guide is parallel with your saw.—Pattern Maker.

[46425.]—**Gelatine Emulsion.**—I inadvertently omitted to state the name of the acid in my reply of p. 69. It was *salicylic* acid.—W. J. Bashford.

[46425.]—**Gelatine Emulsion.**—I have kept emulsion for three months by allowing it to set in a bottle, and when set pouring in about ½in. depth of methylated spirit. I have not tried keeping longer. I have not tried keeping without washing. The best way to wash is to press through coarse canvas, when set, into water. The threads of emulsion thus produced should be kept soaking for one or two hours, the water being poured off and fresh added several times.—H. G. M. Conybeare.

[46428 and 46481.]—**Pumping.**—Square the diameter of plunger, multiply by ·7854, and by length of stroke, and divide by 277. This will give you the number of gallons each stroke (if single-acting) if the pump be full.—Stratheden.

[46428.]—**Pumping.**—Supposing the suction-pipe to be of ample size and the water to follow up throughout stroke, the pump would throw 34·28 gallons at each stroke. Thus: Diameter = 1ft. Square this and multiply by ·7854 (1 × 1 × ·7854) = ·7854 sq. ft. area of piston. This, multiplied by the stroke (·7854 × 7) = 5·49 cubic feet as the volume swept by piston at each stroke. As there are 6·235 gallons in a cubic foot of water at 62°, this volume represents (5·49 × 6·235) = 34·28 gallons per stroke, as stated above.—Glatton.

[46431.]—**Worsted and Woollen Yarns.**—A woollen yarn is stretched, not drawn. By this stretching process all the longest fibres take up a position, forming the core of the thread, and the shortest arrange themselves on the outside of this core at right angles to the thread's length. A worsted yarn, on the contrary, is drawn; all the different lengths of fibres are so mixed that no portion of the thickness of the yarn contains more long wool than another; both core and outside are alike as regards their length of staple, and all the fibres lie parallel to the thread's length. The difference between worsted and woollen is, I believe, not generally understood, some thinking that worsted yarn is made from long wool, and woollen from short. The difference is, however, in the construction of the thread, not necessarily in the material from which it is made.—Worsted Spinner.

[46432.]—**Spiral Spring.**—Wind the wire round a steel or iron mandrel whilst soft, carefully keeping the coils even and proper distance apart; or, wind two or three at once, according to the space required; then all you have to do is to wind them close together. I use steel prepared specially for watch and clock work. I temper as follows: (nothing but practice will, however, make you perfect in the art of tempering, and even skilled workmen cannot always get it right): Heat evenly all over to a red heat, taking care not to burn it, and plunge into tallow, lard-oil, or water; when cold, warm it until it will just melt tallow, and cover with same; now place in fire until the tallow takes fire, and burns without assistance from same; withdraw, shake in air and leave until cold. If you harden in water, spring will be harder than in oil or tallow.—C. M. R.

[46433.]—**Potato-Disease.**—To Mr. Adams.—The potash, in the form of kainit, and fine ground and sifted, should be applied in open drills, above the thoroughly-rotted farm-yard manure, along with an equal quantity of the superphosphate of lime. It is advisable to mix these minerals with dry earth or ashes, so as to dilute them, as we do, at least I, spirits with water; because, in their crude form, they have a withering or burning action on the tender rootlets, such as alcohol on the untanned human stomach. The analogy goes no further. The minerals are digestives to the plant; the alcohol, to the extent it burned off in the animal, is a heat producer. If the manure is not well-rotted, it is better to use none, giving, instead, the same money value in ground bones, bone meal.—W. Adam.

[46436.]—**Chemical Balance.**—"Agricola" cannot do better than get one of Becker's No. 27 balances. It can be charged up to 50 grammes in each pan, and is sensible to 1 milligramme. Price £1 11s. 8d. Becker's English agents are Townson and Mercer, 89, Bishopsgate-street, Within, E.C. Alfred W. Soward.

[46436.]—**Chemical Balance.**—The printer must have mistaken the word "grammes" and inserted "grains" instead. A balance carrying 50 grains would only be suitable for assay and blowpipe work. In Griffin's "Chemical Handicraft," second edition, there is a balance figured, No. 426, which carries 50 grains and shows 1 milligramme; it sells under the price mentioned in your query. A very cheap balance, manufactured by Becker, is advertised in the *Chemical News* every week; it carries 30 grammes, and shows ½ milligramme.—Arthur E. Morris.

[46437.]—**Soda-Lime.**—This is prepared by slaking lime with sodic hydrate in the proportions of 1 of lime to 3 of soda, drying in an iron dish, afterwards heating to redness in a clay crucible; the mass is then broken up and preserved from the air. The action soda-lime exerts upon nitrogen is to convert it into ammonia. This can easily be proved by heating an organic compound with a piece of sodic or potassic hydrate; if nitrogen be present it will be recognised by an ammoniacal odour. I have never known soda-lime from one combustion to be used again; should imagine it would be liable to vitiate the results.—Arthur E. Morris.

[46437.]—**Soda-Lime.**—Soda-lime may be prepared thus:—"Take solution of caustic soda, ascertain its specific gravity, weigh out a certain quantity, calculate the weight of the hydrate of soda present, add twice this latter weight of the best quicklime, allow the lime to slake, and then evaporate to dryness in an iron vessel. Heat the residue in an iron or Hessian crucible, keep for some time at a low red heat, break up the lumps, while still warm, in an iron mortar, passing the whole through a sieve with meshes 3mm. wide. Sift again with a mesh 2mm. wide. The grains which remain on the sieve, and the finer portions which pass through, are kept separately in well-closed bottles. *Tests:* Soda-lime must not effervesce too much when treated with dilute hydrochloric acid in excess; but, more particularly, it must not evolve ammonia when mixed with pure sugar and heated to redness. *Uses:* Granulated soda-lime forms an excellent absorbent for carbonic acid; the powder serves for the analysis of nitrogenous organic substances."—(Fresenius.) The use of soda-lime for such analysis depends upon the fact that most nitrogenous organic compounds, when treated with it, evolve ammonia or a compound of ammonia. The carbon of the organic body is oxidised to carbon dioxide at the expense of the soda, the hydrogen of which, being liberated at the same time, combines in the nascent state with the organic nitrogen, forming ammonia thus: $C + 4NaOH = CO_2 + 2Na_2O + 4H$; and $N + H_3 = NH_3$. Soda-lime is used rather than pure soda, because the former does not attack glass, and is not deliquescent. It may in general be used more than once.—Alfred W. Soward.

[46441.—**Vacuum Brakes.**—I think there is a book on the above by Michael Reynolds (Crosby Lockwood and Co.)—G.

[46442.]—**Launch.**—To "Sunlight."—Fig. 1 will give you some idea of the stern tube and the wood bearing on it. You will note that the shaft passes through first a stuffing-box, and then at the other end through the wood bearing. At that end the stern tube is cast with dovetail grooves in it for the length of the bearing. The dovetails slung up at such a height that there is at least a $\frac{1}{4}$in. between them and the shaft. In these grooves are fitted tightly strips of lignum vitæ which are also afterwards bored out so that there is about a 1-16in. play; the action being that the shaft, as it revolves, carries round a film of water, and hence only bears on the wood when at rest. The top edges of the wood packings should also be slightly rounded off so as not to scrape the water film off the shaft, if we may so express it. I should, for a 1$\frac{3}{4}$in. shaft, let the wood bearing be 8in. long. Next, as to the thrust bearing. I am a great believer in making parts adjustable to take up wear. And I designed the form shown at Fig. 2 to comply with that condition. It is as follows:—The length of shaft where the thrust bearing is to be fitted is turned up a little larger than the other part, and is screwed. In your case, I should let this part be screwed to 2in. thread. In the centre where the bearing comes it is, of course, turned down to 1$\frac{3}{4}$, so as to give a plain bearing. The plummer block is fitted with brasses of extra size in the flange, so as to give the surface required, and the faces of the brasses are also faced off carefully, exactly square and true with the shaft aperture. On the thrust shaft then is fitted two discs with bosses—made to screw on the shaft; whilst behind these go a couple of lock nuts. All being prepared, the bosses are screwed up on the shaft, until the brasses are held between them, and when adjusted the lock-nuts prevent their moving. The same oil-cup that feeds the bearing consequently supplies the thrust discs, and as the wear occurs—and it is remarkably little—it can be taken up by moving the discs and lock-nuts, thus allowing of accurate adjustment. With the usual form not unfrequently from the wear of the thrust bearing the crank shaft, as taking a large proportion of the end strain against its brasses. With this arrangement such need never occur, as the wear and length can be adjusted to a fraction. As to your other query—a screw outside the rudder is decidedly bad. In my opinion, wherever practicable, the screw-shaft should even have an outside bearing beyond the screw.—Sunlight.

FIG. 1

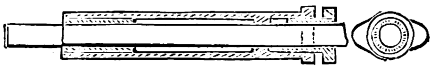

FIG. 2

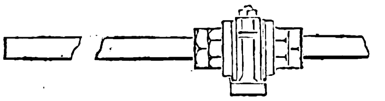


[46443.]—**French Wire-Gauges.**—There are several French wire-gauges: I subjoin a table of the Limoges gauge, with English equivalents in inches, which I extract from D. K. Clark's "Rules and Tables":—

	Diameter.			Diameter.	
No.	Millimetre.	Inch.	No.	Millimetre.	Inch.
0	·39	·0154	13	1·91	·0752
1	·45	·0177	14	2·02	·0795
2	·56	·0221	15	2·14	·0843
3	·67	·0264	16	2·25	·0886
4	·79	·0311	17	2·84	·112
5	·90	·0354	18	3·40	·134
6	1·01	·0398	19	3·95	·156
7	1·12	·0441	20	4·50	·177
8	1·24	·0488	21	5·10	·201
9	1·35	·0532	22	5·65	·222
10	1·46	·0575	23	6·20	·244
11	1·68	·0661	24	6·80	·268
12	1·80	·0706			

—Glatton.

[46444.]—**Press for Moulding Blocks.**—I know of no press proper used in soap manufacture. There is a "barring and caking machine," however, consisting of a series of wire frames, through which the block of soap is forced, which would, I think, answer your purpose.—Glatton.

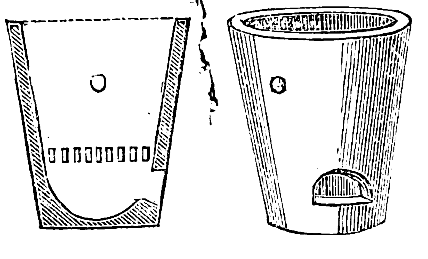
[46446.]—**Soda for Bennett's Battery.**—"W. W. H. G." has apparently purchased caustic potash prepared specially pure "for analysis." What he wants is "commercial caustic soda." I do not know where he can get it in small quantities for 2d. per lb., but have myself bought it at Hopkin and Williams, Cross-street, Hatton-garden, E.C., for about 4d. or 6d. per lb.; I forget the exact figure.—Alfred W. Soward.

[46446.]—**Mr. Bennett's Battery.**—"W. W. H. G." can procure commercial caustic potash from most oilmen for 6d. per lb., which is the price I paid for some. "W. W. H. G.'s" potassic hydroxide is no doubt a tolerably pure sample, quite unlike the dirty, impure lumps commonly known as potash. I set up one cell of Bennett's battery directly after I read of it in the Mechanic; it rings a 2$\frac{1}{2}$in. bell nearly as well as a quart Leclanché. I paraffined the porous cell about one-half from the top, and used an ordinary flat Leclanché zinc plate. The battery is in use, and rings the bell a good many times in the course of the day.—R. Horton.

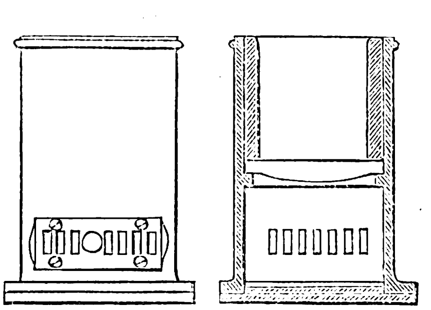
[46452.]—To "**Finem Respice.**"—The small size of camera and Darlot's portrait-lens referred to, would give a very unsatisfactory picture of the scenery named, but if a camera were made the same size as referred to in my later reply (35087, page 402, No. 718), it would answer well with an ordinary landscape-lens, and (though I have not tried it), I fancy the "meniscus" advertised in this paper by Mr. Lancaster for, I think, 5s., would give a very satisfactory picture; perhaps he will supplement this with a few words on it. (2) 1-32nd of an inch is quite thick enough for the size named; if well fitted, it would be light-tight; but in a 5in. one I made, I put a double tube for the front-piece for the back to slide between the tubes, fastening the latter together with solder, and a ring of wire at front end. (3) Darlot's 1in. portrait lenses can be purchased with rack and pinion, but are not fitted with stops. I do not think rack and pinion can be got separately.—Finem Respice.

[46460.]—**Tortoiseshell.**—Boiling would soften the shell, but it would become hard again when cold.—Glatton.

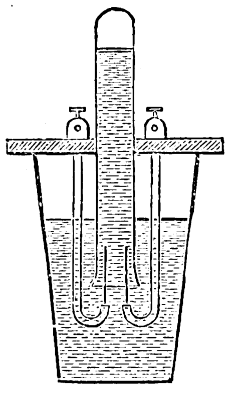
[46461.]—**Charcoal Furnace.**—A simple furnace can easily be constructed out of a black-lead crucible. Procure a crucible about 11 or 12in. high, cut an opening at the bottom of one side, as shown, also two round holes, about an inch in diameter, opposite each other, half-way up the sides; get a small grate, large enough to rest inside, just above the lower opening, and the furnace is complete. The sketch shows it both in perspective and sectional views. Using charcoal with this furnace all the ordinary operations of distillation, crucible work, and heating tubes can be performed. With such a one as just described I have melted silver, using a small ordinary bellows.—Arthur E. Morris.



[46461.]—**Charcoal Furnace.**—As the information may probably be of use to more than the original querist, I send a sketch of a form I designed originally for the use of a large college; it was one of the conditions that it should be of such a form that all necessary patterns should be made by the students, and that the castings should not require to be turned or fitted in any way. As such would, therefore, be similar to the requirements of many amateurs, I venture to crave the necessary space for it. As will be seen, the outside is a cylindrical pillar, with a bend, as a matter of ornament, at top, and a flange at the bottom. Inside there is a projecting ring, as shown in the section, cast in one with the body part. Resting on the ring is the circular firegrate. The upper part is lined with Fletcher's non-conducting composition, which not only keeps the outside cool, but also greatly economises the heat. Air is admitted through a series of vertical slits to the space underneath the grate bars. This was the design as originally proposed, but two further additions have been applied; one is that the air supply is adjustable. And this is done by a casting made to fit the curve of the furnace body, with slits in it that come fair with those in the ash-pit when it is to the extent of its traverse one way, whilst, if pushed the reverse way, the air is entirely cut off. This plate is carried by four screws passing through elongated or slotted holes, and screwing into the furnace-body. I now give form of handle to actuate it with; and a final addition has been made in the shape of a circular casting, as shown, to form a bottom to the ash-pit. It is formed with a slight projection, which, passing into the furnace-body, prevents any chance of slipping off sideways. If any reader would desire to make one, I shall be happy to give further details or information which may be asked.—Sunlight.



[46462.]—**Measurement of Electric Current's Strength.**—The strength of current varies directly as the amount of water it will decompose in a given time. Make a voltameter as follows: take two pieces of guttapercha-covered wire, solder a piece of platinum to one end of each, and with a hot wire spread the guttapercha over the joint, leaving the rest of the pieces of platinum clean; fill a test-tube with water, to which a little sulphuric acid has been added, and suspend it mouth downwards in a tumblerful of the same acidulated water. Bending up the ends of guttapercha-covered wires, insert the plates beneath the test-tube, but take care that they do not touch one another; pass a current from, say, a couple of Grove's cells from one wire to the other, and note how long the top level of water in test-tube takes to fall, say, $\frac{1}{2}$in.; now remove cells, and connect dynamo machine in their place. If the level falls twice as fast as before, the machine gives twice as much current as the two cells, and is equal to (2 × 2) = 4 cells, and so on. This is equally suitable for dynamos giving a continuous current or an alternate one.—Glatton.



[46464.]—**Steel Rails.**—The ordinary weight of rails now used on cross-sleepers is from 75lb. to 85lb. Generally the wedge is placed on the outer side of the line of way, but on some railways it is placed on the inner side. The latter position is to be preferred; for should the wedges from any cause drop out of the chairs, the gauge of the railway, which in that case is determined by the outer jaw of the chair, and not by the key, cannot be deranged by the wheels forcing the rails outwards. Platelayers also, in walking along the line for the purpose of examining the permanent way, can see the keys of both rails at once if they are placed on the inner side. Moreover, if the wedges are on the inner side, the outside jaw of the chair can be carried up well under the shoulder of the rail, and unyielding lateral support be thus given to the rail near its top.—G.

[46469.]—**Toning.**—There is no published mode of toning platinotype prints that is entirely satisfactory; but by modifying the heat of the developer, and especially if the negative be somewhat thin, the print partakes of a brown tint.—W. J. Bashford.

[46473.]—**Pressure of Water.**—The weight of a cubic foot of water at 62° is 62·35lb. The pressure then on a strip 1ft. wide and 8ft. deep varies from 0 to 8 × 62·35 or 498·8lb. per sq. ft. The mean pressure on this imaginary strip is 498·8 / 2 = 249·4lb. As there are 12 of these strips in the width of the gate, the total pressure is (219·4 × 12) = 2292·8lb. At 2ft. from the bottom or 6ft. from surface, the pressure per sq. ft. = 6 × 62·35 = 374·1lb.—Glatton.

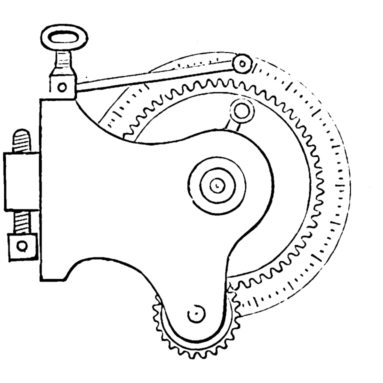
[46475.]—**L. & N. W. Engines.**—Atlas, Nov., 1874; Councillor, Nov., 1861; Wyre, 1878; Simoom, Sept., 1874; Vizier, Aug., 1874; Vulture, Nov., 1878; Viscount, Sept., 1873; Lawrence, Nov., 1880; Medea, May, 1879; Lapwing, Oct., 1878; Arab, Sept., 1874; Python, Oct., 1874. The others I do not know.—Diomed.

[46481.]—**Boiler-Pump.**—I fear that "Slocum Podger" will land rather wide of the mark by doing as he proposes; and even supposing his suggestion was to be followed, would his answer be expressed in gallons, inches, feet, or what? Perhaps the following rule will help him a little; but in addition to the length of stroke and diameter of ram, he will require to find how full the pump is at each stroke. (1.) Find the area of the horizontal section of the pump by multiplying the square of the dia. by ·7854. (2.) Multiply this by the number of inches in stroke. (3.) Multiply this product (2) by the amount the pump is full, and the result will be the quantity of water (in cubic inches) delivered at one stroke. For example: Pump, 2in. dia.; length of stroke, 6in.; pump, three-quarters full at each stroke. $2^2 \times \cdot7854 \times 6 = 18\cdot8496$ cub. in.; $\frac{3}{4} \times 18\cdot8496 = 14\cdot1372$ cub. in., or almost $1\frac{3}{4}$ gills at each stroke.—WAS-HEIL.

[46482.]—**Gregorian or Cassegrain.**—The radius of curve for the concave may be 54in., that of the convex 12in. This combination will have an equivalent focal length of 10ft. 9in.; therefore, with a 1in. eyepiece will be a power of 129, or with a 2in. eyepiece $64\frac{1}{2}$. My experience is that the "Cassegrain" is a most interesting form of instrument, but by no means easy to construct, so if you were about to make a telescope entirely I should say, have a "Newtonian"; but as you appear to have tube stand and adjustments, I see no reason why you should not try to complete it by adding the speculum. I am afraid you will not be satisfied with the performance of spherical curves; if not, you can alter them afterwards when you have more experience; the quickest way of getting a small convex is to buy of an optician a lens of the required radius.—A. N. H.

[46484.]—**Lathe.**—The way I should get over the difficulty you mention would be as follows:—Take off the speed-cone of the headstock, and turn off the edge that goes against the gear-wheel fixed on the mandrel, say $\frac{1}{8}$in., so that, if now replaced, there would be $\frac{1}{8}$in. space between the gear-wheel and the speed-cone. Your lathe being small, it is, no doubt, driven by either a V or round belt, so that you would simply turn away the blank part left at the end of the speed-cone beyond the largest speed. Next, get a piece of hard brass-plate, and fit it to go between the speed-cone and the gear-wheel, fastening it to the latter with screw-pins. It will, therefore, project into the space between the gear-wheel and the shaft over the back-shaft, and by cutting away part of the circular division-plate, the locking-bolt now in use need not be disturbed. You have now only to get the rows of holes drilled, and you are complete. I do not like the plan of clamping the speed-cone to the gear with a nut, as it is likely to slip, and besides, throws great longitudinal strain on the mandrel, which, if small, is sometimes sprung by it, and thrown out of truth.—SUNLIGHT.

[46484.]—**Lathe.**—To "E. F. C."—The best way of fitting division-plate on "E. F. C.'s" lathe



is to put it at the back of front gear-wheel, and let it project as far as there is room between lower edge of gear-wheel and lathe-head casting. The back of gear-wheel will have to be recessed the thickness of plate as far towards centre as the bolt which binds it to pulley will permit, and the pinion which gears with it will also have to be recessed at back, so as not to get foul of division-plate. The plate may be fastened to gear-wheel with either screws or rivets. My own lathe has its division-plate fitted thus, and the plate projects $\frac{1}{2}$in. beyond teeth of wheel, which is sufficient for one row of holes. But by having 360 or 240 holes lined off into tens and fives, it is sufficiently convenient. When using division-plate I always, beforehand, mark off with a white chalk pencil the holes I wish to use, so that I never make a mistake. If "E. F. C.'s" front gear-wheel has a wide enough margin inside teeth, it might be easier to divide it than to have a plate put on. Most certainly 3-16in. would not be sufficient space to put a nut behind pulley. I send a diagram of my arrangement.—F. W. G.

[46485.]—**Pedal Organ, &c.**—The pedals of an organ with one manual are usually made to bring down the keys of the lower or bass portion of the manual. I should decidedly conclude that if a set of pipes were added to an organ of the size you name, they should be of 8ft. pitch, open diapason, metal. If a 16ft. pipe were added, the treble would be overbalanced in an organ containing such a limited number of pipes. If you desire to have a 16ft. pipe on the pedal, it would be advisable to increase the number of pipes on the manual, more particularly in the treble portion.—G. FRYER.

[46489.]—**Bicycle-Making.**—If I was about such a job, I should make the parts a fair fit, and braze only. In some ways a pin would be a help, but if properly done, the brazing should run round in the joint, forming a solid metallic joint, nearly as strong as the iron, and would far rather spend the additional time in making a fair fit for brazing only than the reverse, and use a pin to make good what I knew was bad work in the fitting and brazing. What other parts do you want assistance as to the construction of? If you had gone the right way to work, you should have bought certain parts ready fitted. That is to say, I should buy the hubs in the rough, but all drilled for tapping, &c.—SUNLIGHT.

[46486.]—**Baking.**—A bakery capable of turning out 70,000lb. of bread a week, presupposes the consumption of between 175-80 bags, of 280lb., of flour in the same time. For a business of such magnitude, machinery driven by steam-power should be employed in kneading the dough. The mixing-machines are various in shape, as also are the mixers revolving, some single, some double, inside them. As these are generally known by the name of the makers, it would simply give men who are well able to pay, a gratis advertisement to name any of them. If Mr. [illegible] Washington will advertise his address in this paper, I will send him the names of several makers of baking machinery. The best style of oven depends on the style of bread to be baked in it. As to how heated, Mr. Washington will find in *The Miller* for April a paper from my pen on "Ovens Heated by Gas-Coke," along with working plan and section of a line of three ovens.—W. A. THOMS.

Prof Tyndall on Sound, Light, and Heat.—On Thursday week Prof. Tyndall delivered the second lecture of his course at the Royal Institution. The explanations given by Huyghens of the phenomena of reflection and refraction, as well as of the properties of convergent and divergent lenses had, he said, been fully verified by the progress of time and science. The lecturer showed that there are sound-lenses also, and that the wave theory affords a no less adequate explanation of their properties. He demonstrated by the test of the sensitive flame that cotton net, because porous, transmits waves of sound, while the interposition of a non-porous body leaves the flame unaffected. Just as the passage of light was hindered by clouds, although the air and light of which these are made up were alike transparent, so acoustic clouds obstructed sound. Acoustic clouds consisted of layers of heated air with intermediate layers less heated. The lecturer formed an artificial cloud of the kind, which was shown to intercept sound; the sound was thus thrown back in miniature echoes. Another analogy between light and sound was brought out by comparing the solar spectrum with a scale of notes produced by striking a graduated series of tuning-forks. To illustrate Dr. Wollaston's observation, that certain sounds are inaudible to many ears, Professor Tyndall blew a small whistle, whose low, though shrill, note instantly agitated the sensitive flame, while full half of those present, as a scientist had predicted in conversation with the lecturer beforehand, heard nothing. Resemblances were also pointed out between the absorption of light and that of sound On the sound struck from one tuning-fork being quenched, it was proved to have been not annihilated, but simply absorbed by an adjacent fork. In like manner the yellow ray in the solar spectrum was absorbed by sodium vapour as the metal passed under the eyes of the audience into that form, leaving the place of that colour in the spectrum marked by a black band. Professor Tyndall concluded with an eloquent and generous tribute to the memory of his predecessor in the chair of Natural Philosophy at the Royal Institution at the beginning of our century, Dr. Thomas Young, who not only put into Champollion's hands the key to the Egyptian hieroglyphics, but anticipated by a score of years Fresnel and Arago, as was urged in detail, in placing upon its true scientific basis the undulatory theory of light. The lecturer repeated Young's brilliant demonstration of the fact that the prismatic colours of the soap-bubble are in the exact ratio of the density of the film, ranging from the white light where the cuticle is thickest to the violet ray as it darkens to black just at the bursting point.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "C. M. R." has replied to 45766; W. Bashford, 45962; W. H. Scriven, 45964.

45792. L. and N.W. New Tank Engines, p. 482.

QUERIES.

[46492.]—**Horizontal Winding Engines.**—To "CARINO."—I am about to replace a pair of horizontal winding-engines, cylinders 28in. and 4in. stroke, and the boiler-pressure 60lb. per square inch, and working with slide-valves. Which type or class of valves would you recommend me to put to the new cylinders, as there are winding-engines at the present day working with slide-valves, Cornish, and piston-valves? Please favour me with your views of the object of putting piston-valves to winding-engines, and the durability of the same. Also, what should be the distance of slot-links, and the distance from centre to centre of the same for connecting the eccentric-rods on the same. The throw of the eccentrics is $4\frac{1}{2}$in., and the stroke of the valves $3\frac{3}{4}$in. I am working the above with weigh-shafts and levers, and the slide-valve boxes are on the back end of the cylinders. As I am about to replace the above, would you recommend me to put the nozzles on the side of the cylinders, and the slide-valves midway of the same, and to work them direct from the eccentric-rods, and to have the stroke of the valves equal to the throw of the eccentrics?—S. E. D.

[46493.]—**Lathe.**—I want a treadle-lathe to cut wrought-iron and steel, 1in. × 1in., as quickly as possible. Will "Sunlight" advise as to dia. and weight of fly-wheel, dia. of back-gear, gut or strap? Prefer gap and screwcutting.—LONG TOM.

[46494.]—**Deafness.**—I addressed a query to Dr. Edmunds on this subject, but I presume it escaped his notice. May I draw his attention again to my case?—I am afflicted with deafness of about three years standing, and during that period it has been gradually increasing. A London aural surgeon, after an examination, gave the cause as swelling of the aural tract on both sides. I attended a hospital here for six months; but without benefit. An incision was made into the tympanum, but no beneficial result followed. The medicines that were prescribed were tonics and alteratives; and I was told the cause was chronic inflammation of the tympanum, and an accumulation of mucus. As I derived no benefit from the treatment, I have discontinued attending for about six months; but I find that the deafness is increasing, and have exhausted all the resources for relief in this place. I trust that Dr. Edmunds will please to take notice of this, and reply.—AURIS.

[46495.]—**Silicate Paints.**—Will anyone that has had experience in using the transparent silicate paints for waterproofing porous stone or brick inform me what they think is the best method for applying it, and what they would recommend for stopping the joints, or any other information regarding the same?—M. P.

[46496.]—**Sewers.**—Would "J. C. S. B.," or any other, kindly give me the working, showing how the hydraulic mean depth in a sewer is arrived at? I am in a fix in working out answer to query 45569 in "E. M.," Feb. 17th, to formula—

$$V = 55\sqrt{R \times 2H}.$$

I shall be very thankful for an early answer to the above—SANITARY STUDENT.

[46497.]—**Fortified English Cities.**—I should feel glad if you or any of your readers could give me a little information respecting the towns and cities of England that were formerly fortified or surrounded by walls. We read of the walls of London, Chester, and one or two other places; but what I wish to know is, what other towns were similarly protected, when they were so surrounded, and when were they dismantled? In Leicester, I find there are reminiscences of fortifications by various streets having their names terminate by the word "gate," as Humber-gate, Belgrave-gate, &c.—ANTIQUARY.

[46498.]—**Cement for Glass.**—I am out of employment, and a gentleman has offered me three months' work if I can do it, that is, to fix upon windows glass coloured transparencies. What I want is, a cement to do the same. Will any kind reader oblige with recipe of a cement to fix coloured-glass transparent advertisements: one that will resist the condensation of windows and outside weather.—THOS. GREEN.

[46499.]—**Lathe.**—Having essayed to fit up an amateur lathe, I have bought, as a start, a crank 5ft. 3in long, $1\frac{1}{4}$in. thick, and 3in. throw, and a driving-wheel 2ft. 2in., and three grooves, with a smaller one near the boss. Now the hole in boss of wheel is not large enough to go on end of crank by $\frac{1}{4}$in., and there are transverse half-round notches on the front of boss of wheel, as if to receive studs through arm of crank to keep wheel on.

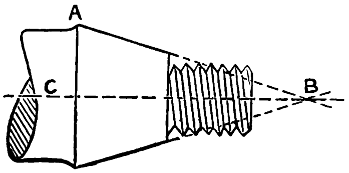
Now, would someone say whether that is the proper way to fix wheel on, or how otherwise? Also, whether my crank should run in metal bearings, or on steel centres? A six years subscriber would be obliged.—J. P. F.

[46500.]—**Cement for Cards.**—Can any correspondent oblige me by giving the composition of the cement used to cement the layers of cloth together in the cards or fillettings used for carding cotton, &c.?—F. L.

[46501.]—**Length of Exposure.**—What length of time should a gelatine plate be exposed when using a small stop on a landscape? Supposing I exposed a plate with full aperture for one second, using a Ross 8×5 lens, what exposure should be given with stop No. 5, and so on, up to No. 1.? I cannot find any instructions on this subject in any book I have seen on photography, and it would be rather an expensive experiment to determine.—Beginner.

[46502.]—**Proportioning Slide-Valves.**—Will some reader illustrate the application of Zeuner's diagram to cases in which there is *negative* inside lap? Also the diagram on p. 537, Vol. XXXIV.—Glatton.

[46503.]—**Jamming of Tapered Journals.**—The figure represents the tapered journal of a lathe mandrel. Assuming the angle of repose of lubricated steel surfaces to be 8°, what should be the taper of mandrel in order that it may be on the point of sticking fast? Should the angle A B C, or the angle A B D, be 8°?—Glatton.



[46504.]—**Air and Steam.**—Two empty vessels fitted with air-tight cocks are filled, one with steam at 248° Fahr., two-atmospheres pressure, and the other vessel is also filled under the same pressure of two atmospheres with hot air, which is also heated up to 248°. The two vessels are connected together by a tube, and the cocks opened. It is supposed that no heat whatever is lost through radiation. 1. What will be the pressure in the vessels after the communication is established? 2. Will there be any condensation of steam? 3. If the mixture of hot air and hot steam at 248° was compressed to, say, one-half or one-third of its volume, would there be any condensation of steam, supposing there is no loss of heat? Kindly explain and oblige—Total Heat.

[46505.]—**Movable Stage for Theatrical Performances.**—What would be the best way to construct a movable stage upon a series of tables as a foundation, but about 18in. higher, in a manner capable of being put together and taken to pieces with the least possible trouble, as it may be required but for one night, but oftener for two or three nights together? therefore, simplicity and strength are the chief points to be borne in mind. Size about 36ft. wide by 24ft. deep; and for convenience of storage, any kind of form or tressels should be dispensed with. If dimensions of the timber recommended, and probable cost could be given, it would be of great assistance to—Platform.

[46506.]—**French Polish.**—Will some correspondent kindly give me a few hints on reviving French-polished work? 1. How am I to repolish scratched furniture? Is it necessary to sandpaper to get the scratches out, and then repolish, when there is a good body on the work? 2. How shall I proceed when patches of polish have been removed, so as to bare the wood? Can I repolish the patches without having to go over the whole? 3. In bodying up work, can I use fine plaster of Paris or precipitated chalk to sprinkle over the work instead of pumice-powder? 4. What is used for the edges of fretwork when the wood has been polished before being cut? At present the edges look as if they were covered with dust.—Amateur Polisher.

[46507.]—**Wax.**—I should be glad if someone would tell me if there is a transparent wax [and if so, how is it made] which could be used for waxing fine-coloured silks without destroying the colours? What wax do anglers use for making artificial flies?—Silk.

[46508.]—**Lime-Burning.**—I have on my farm a quarry, from which we get a stone composed chiefly of small sea-shells, fossilised, which lies in ledges, and is got out with a pickaxe. Now as it is a long way and a bad road to a limekiln, I thought I would try some of our stone in the kitchen fire, which I did, and made very good brown lime, slacking to fine dust; but when made into mortar it did not dry as hard as might be wished, but still it would do. Thinking as we have much heavy land about here, that it would improve it if it was limed, and as it is out of the question to bring lime here, I might make some, I built a kiln to hold about a quarter, intending, if it improved the ground much, to build a larger one. The kiln was connected with the brewhouse chimney, to make a good draught and perfectly airtight. This was carefully filled with stones laid edgeways with coal between (as much coal as stone), with a hole all the way up middle for smoke. When lit, it burnt well—even roasting somewhat; but when emptied next day, the stones would not slack at all, appearing to be only blackened through, though very rotten. Will someone kindly give me assistance?—What are these stones: they appear to have been formed by the sea, as there is a long valley just below where they are found, as if washed out by the sea? I have tested the lime with spirits of salts, and it leaves a small residue. How can I find out what this residue consists of?—as it may be valuable as manure. What is the reason I can make lime in the grate and cannot in the kiln—is it too small? If so, what is the smallest quantity that can be burnt? Was not the heat great enough or not kept up long enough, as it was not burning more than six hours? What degree of heat is necessary, and what shade of redness is it? What proportion of coal does it take to stone? How long should it burn? Also, is there anything I could put with mortar, or do to make it harder? Any advice on above will be thankfully received by—Peter.

[46509.]—**Analysis of Soil.**—Will anyone please give me some plain directions to make a quantitative analysis of soil, and also say of what a good soil should consist? Is there any good work (not expensive) on this subject? I have a fair knowledge of the principles of chemistry; but the books I have on agricultural chemistry say but little on the methods of making analyses.—High Farmer.

[46510.]—**Photography.**—Will Mr. Lancaster, or any other kind friend, please give me instructions for making a very simple and efficient changing-box for dry plates? I want to use it when out landscape taking. All I require is some contrivance whereby I can take out two dozen plates at a time, and change them in the field. If possible, to be used with ordinary dry-plate slides, and have no elaborate mechanism, and be as inexpensive as is consistent with efficiency.—F. C.

[46511.]—**Stains in Dry Plates.**—How can I avoid or remove the dark yellow colour imparted to some negatives by the pyro-developer? I have lately heard that ordinary tin dishes are safe to use for developing in. Can anyone tell me if the chemicals chiefly used for developing have any effect upon tin, or tin upon them? As if not, it would be a very useful article to me to make dishes of for developing?—F. C.

[46512.]—**Boring Horizontal Bars.**—Can any reader inform the inquirer how ash horizontal bars are bored for inserting steel core?—Gymnastic.

[46513.]—**Drill.**—Would "Jack of All Trades" be kind enough to tell me what would be the best kind of drill to bore a ½in. hole 3ft. long in a wrought-iron bar? and oblige—W. G. S.

[46514.]—**Wood Turning.**—Will some correspondent describe a chuck suitable for boring the hollow in a wooden vase? As I am only a beginner in lathe work, a small sketch will oblige—Fond of Woodturning

[46515.]—**Cast Malleable, or Annealed Cast Iron Castings.**—What is the nearest approach to these (for toughness and durability) which can be cast direct from the furnace? Is it possible to mix malleable iron along with the cast-iron, and thus make a tougher and stronger job, and in what proportions should they be mixed? What I want cast is, a number of small hooks, section ½in. × ¼in., weighing each about 1lb.—Iron.

[46516.]—**Caledonian Engines.**—Will "Carstairs" give principal dimensions, dates of original construction, and makers' names of the different classes of tender engines used for passenger traffic on the Caledonian Railway? I observe in a former letter he gives the original Greenock-built engines as having 22in. of a stroke. I am under the impression that their stroke was only 20in. A detailed account of these little engines (should "Carstairs" or anyone be in a position to give it) I am sure would interest many of "ours."—Netherby.

[46517.]—**Preserving Wood Troughs.**—Will any reader kindly tell me of any substance better than paint for preserving wood-troughs 3ft. wide and 6in. deep, to carry waste hot-water?—Painter.

[46518.]—**Cotton Wadding.**—Will any reader kindly inform how to make what is sold in drapers' shops as cotton-wadding?—Painter.

[46519.]—**Kirk's Double-Expansion Compound Engine.**—Will someone explain the principle on which this works? How is it that expansion of steam in two cylinders is more economical than in one?—Shipowner.

[46520.]—**Gas-Engine for Launch.**—I notice in a circular recently issued by "Sunlight," that he says his gas-engine will, when running, by a small additional appliance, produce its own gas. Would not an engine of this sort be the very thing for a launch, as it would be about the same size as an ordinary engine, and would dispense with a boiler and its accompanying troubles? What does "Sunlight" say to this?—Cwmbu.

[46521.]—**Emigration, South Africa.**—I am thinking of going out. I am informed that Dutch is chiefly spoken. Would any kind reader advise a suitable book on that subject? Would a person having a fair knowledge of telegraphy have any difficulty in obtaining employment? Any relative information would be gladly received.—F.

[46522.]—**Oil-Extraction by Carbon Disulphide.**—Would any reader of the Mechanic favour me with a description of the plant most commonly used for the extraction of oil by carbon disulphide; and, if possible, with a diagram? Where can I find articles relating to recent improvements and inventions for the above purpose?—G. D.

[46523.]—**L. & N.W. Engines.**—Will some reader give the dates and sheds of the following engines?—Kestrel, Quail, Crane, Di Vernon, and Redbreast.—Diomed.

[46524.]—**Air Pump.**—I should be glad to know if there is any method of pumping air to a pressure of 15 or 30lb. to the sq. in. by means of water or mercury falling from a height through a tube, after the manner of a Sprengel air-pump? Also, could anyone give me plans or description of such an apparatus, together with a formula for determining the pressure, having the height of the fall?—Robur.

[46525.]—**Botanical.**—Could anyone inform me if there is any way to prevent flowers, such as the white water-lily, and various kinds of leaves, from becoming brown while being pressed for botanical purposes? In *Science Gossip* for last month, a solution of potash-alum is recommended for microscopical purposes. Would this solution prevent flowers and leaves from losing their colour while being pressed previous to mounting? I have tried a mixture of spirits of wine and water; but this does not answer very well. I should be glad to know anyone else's experience on this subject.—Robur.

[46526.]—**Removing Spots from Telescope Glass.**—The spots are of a darkish brown colour, and vary in size to about ⅛in. They are on the side of the glass which is opposite to the eye when viewing anything, and can be seen best by taking the glass out and looking at it sideways. The glass is 2in. in dia., and about ¼in. thick, and is marked "Bardow." As the spots are a great inconvenience when looking at anything, any information how to remove them will oblige—G. H. Corbett.

[46527.]—**Memorandum Tablets.**—Will anyone inform me of the process of coating cardboard with a surface that will take lead-pencil marks and also bear the removal of these marks by water? Tablets of this kind sold are covered with a creamy-white enamel.—Ixion.

[46528.]—**M.R. Locos.**—Can Mr. Stretton or any correspondent say which is the best—to have a bogie in front, or a pair of leading-wheels? Which do the Midland Railway find the best in ordinary working? An answer will oblige—F. C. B.

[46529.]—**Varnish for Violin.**—What should be mixed with fine pale French oil-varnish in order to bring it to the colour usually seen on modern French violins? I believe the cheaper kinds of these instruments are generally stained and then French-polished; but this is not what I require. Is there any dependence to be placed in violin dealers? The recent case of "Hodges *v.* Chanôt" would lead one to doubt it.—War.

[46530.]—**Rotary Water-Motor.**—I have been thinking of making one of these to drive a small lathe. I have a good water-pressure about 60lb. per sq. in.; but I should have to pay the Corporation for use of water, and I want to have a motor which will be most economical with water, and give good power. I think a fan would cause too much waste, and wish to avoid it. Hagg's motor is too dear; so I want to make something simple that will do the work. Can any brother-reader give me help? I can have ½in. or ¾in. pipe.—Bob.

[46531.]—**Yacht Deck.**—Can any person tell me what is the best wood for decking a 20-tonner? I have been advised to use yellow pine. Would not pitch be better? What would be the best size for the planks? What is the best way to fasten down deck?—Yachtsman.

[46532.]—**Confervæ on Portland Cement.**—What is the best way of preventing the growth of confervæ on the Portland cement lining the basin of a fountain containing gold and other fish?—E. M. Holdis.

[46533.]—**Coal-tar Soaps.**—To Dr. Edmunds.—What is the hygienic effect which these soaps produce? I ask, because I understand that, according to some, these soaps act as preservatives against infection, and as specifics in various skin-diseases. My difficulty is: How can soap produce any marked effect, when the greater part must be rubbed off in drying?—Housekeeper.

[46534.]—**Cod-liver Oil.**—To Dr. Edmunds.—I have seen it stated that "light brown" oil is much better than any other; and, on the other hand, have been assured that the cheap oil which is to be had at many fishmongers' is just as useful as the most expensive kinds. Which statement is correct? I have got more good from one bottle of De Jongh's than from a dozen of the other kind. Is this a matter of constitution, or an accident due to my having obtained inferior oil?—Delicate.

[46535.]—**Name of Star.**—In Gall's "People's Atlas of the Stars," there is entered, within the boundary of Cepheus, a fourth-mag. star, to which is assigned the number 4 β. In Mr. Proctor's atlas the same star is included in Ursa Minor, and numbered 2. Is the entry in Gall's atlas an error, or was this star formerly included in Cepheus?—Cepheus.

[46536.]—**Shaft.**—Having occasion to extend, I propose driving a shaft with belt off the main shaft. The main shaft is 10ft. above the other shaft; but I find they are not in line by about 30in. in 25ft. They are perpendicular or cross where I propose to put the belt on. Will the belt work? Perhaps some of your obliging readers can solve my difficulty.—G. O. W.

[46537.]—**Miniature Spectroscope.**—To Mr. Lancaster and Others.—Will you kindly tell me how to make a portable spectroscope which will show the double line D distinctly? Shall I require a compound prism, and is it possible to make one of Canada balsam? The ordinary balsam has a yellowish tinge, and is rather opaque—would it do? I should like a sketch of the arrangement of prisms, &c., inside the tube. The numbers of the "E. M." containing the instructions are out of print—Thylbe.

[46538.]—**Utilising Water-Power.**—To "Sunlight" and Others.—Given a spring running 2½ gallons per minute, fall 42ft. in about 300 yards of 1½in. pipe, what would be the best size for the fan-wheel of motor, speed of same, and diameter of jet? What would be power in foot-pounds per minute? Please give rule, or refer to some book. I have one of Weale's books on turbines, but it does not mention the "Thirlmere" class of motor.—J. Hezmalhalch, jun.

[46539.]—**Water Power and Electric Light.**—To "R. P."—"Sigma" thinks I asked too much in my last query. I, therefore, wish you to kindly read over the query appearing above this, and to give your opinion as to whether there is power enough to maintain one incandescent lamp by the use of a dynamo, with or without storage batteries? What horse-power is necessary for one incandescent lamp? I hope we have not heard the last from Dr. Caplatzi on this subject.—J. Hezmalhalch, jun.

[46540.]—**Infant's Food.**—Will Dr. Edmunds kindly state most suitable food for infant three to four months old in combination with mother's milk? Also, please state if a food composed as follows would assist in forming brain, bone, nerve, and muscle, say, in following proportions?—One part wheat flour, one oatmeal, one arrowroot, pinch of salt, boiled for quarter of an hour in sufficient water to form a jelly, afterwards fresh milk added to thickness of cream. Suggestions will exceedingly oblige—Sigvald.

[46541.]—**Ants in the Garden.**—I reside in Madrid, Spain, and my garden there is infested by ants, which I find most injurious to the plants, grass, &c. I have been recommended and tried a vast number of things to remove them; but without effect. Could you tell me of anything that would remove them altogether?—Negs.

[46542.]—**Broken Steam-Gauge.**—To "Sunlight" and "Jack of All Trades."—I have a steam-gauge. It has on the face, "Bourdon's patent, Schäffer, Budenberg," and the tube inside is split about 1in. down one side. Will you please say how I can mend it, or is it useless? Also, will you please give instructions how to make a mercury-gauge?—Gaugle.

[46543.]—**Executors and Legatees.**—To Mr. F. N. Wetherfield.—Some five years ago a widowed mother died, bequeathing all her property to her two daughters, the younger being then about 18 years of age, and the elder over 21. A distant relative, an uncle, was appointed sole executor, and it was provided in the will that he was to take charge of and be responsible for the younger daughter's half until she became of age. By this time she is, of course, 23 years old, and she cannot get an understanding at all with her uncle about her money; neither can she get him to give it up. About a year ago he gave her a piece of notepaper, signed by himself, saying, that on behalf of her deceased mother he held the amount due to her by the will. What I want to know is—(1) Should anything happen to her uncle, would she get her money? (2) Is the paper he gave her of any legal value? I should state that it is not witnessed by anyone, neither is it stamped. And lastly, what course is best to pursue under the circumstances? She has no brother, and only one sister, and is comparatively helpless.—A Deeply Anxious One.

[46544.]—**Glass rendered Dim by Fumes from Spelter Works.**—The fumes from a spelter works have caused the window-panes of our drawing-office to be covered with a yellowish film of some substance. It requires such scraping with a knife to get it off, that it makes it very laborious. Is there an acid that would remove it?—Engineering Student.

[46545.]—**Purification of Water.**—In last week's *Chemical News* an account is given of the somewhat remarkable results of a new mode of purifying contaminated waters, and rendering them absolutely pure and fit for use. Can any of your chemical readers give any further information on this subject, as to whether it is a secret or a patent, or whether the advantages of so great a boon are possible to be obtained in a locality where the water is far from pure and wholesome?—A. Lloyd.

[46546.]—**Moulds for Glass.**—Can any plastic material, such as fireclay, be used for pressing molten glass, or can any such material be used for backing a thin copper mould?—A. Trotter.

[46547.]—**Jewelry Repairing, &c.**—Will any of "ours," who have been so kind of late in giving us information on all kinds of jewelry repairing, &c., tell me the best way of removing old rivets from brooch joints? Also, how to enlarge holes in new pins, as I find them often much too small, and how to put good point on pin when obliged to shorten? Must I hard solder catch and joint on silver coins for brooches? If so, please tell me the best way, and what solder to use? Also, what kind of joints and catches?—Blue Gown.

[46548.]—**Coned v. Grooved Pulleys.**—Is it correct that round belts running in V-grooves transmit more power than flat ones running on coned pulleys? And if so, why are they not used for heavy machinery? What is the proper angle for V-groove, and should the belt bed to bottom of groove, or not?—M.

[46549.]—**Science Questions.**—Will one of your chemical contributors kindly devote a few leisure minutes to the solution of the following questions in honours?—1. A gaseous mixture consisting of the following constituents: Oxygen, hydrogen, carbonic anhydride, hydrochloric acid, carbonic oxide, and nitrogen. Describe minutely how you would determine quantitatively each of these gases. 2. Required the percentage of strontium in a mixture of the carbonate of strontium and calcium, 1·3332 grams of which yielded on treatment with hydrochloric acid 0·5104 gram of CO_2.—Test Tube.

[46550.]—**Instantaneous Photography.**—Many thanks to "Baboon" and J. Bushford for their replies. In speaking of photographing a train, I meant broadside on, and understood an express had been so taken. How about Mr. Muybridge's galloping horses? Now that you have settled the difficulty of very short exposure, will you kindly tell me if any plate can be made sensitive enough to produce a good negative with only 100th of a second's exposure? I should like to know what plates will do, as I have not been able to obtain a sufficiently-exposed plate, using Swan's 20 times, and taking off the cap and putting on again as quickly as possible? Is any special mode of development used?—F. C.

[46551.]—**Unseasoned Wood.**—Can any of our correspondents furnish a method of testing whether wood is unseasoned or not in furniture, &c.?—G. Fryer.

[46552.]—**Loosening Green Baize.**—How can I get off baize cloth that has been glued on the inside of a desk?—G.

[46553.]—**Riveting Copper Boiler.**—I am making a small riveted copper boiler, and have succeeded in riveting the body of the boiler and one of the ends. My difficulty is, that I see no way by which the rivets joining the other end can be held in place whilst they are hammered. Will some reader give instructions how to proceed? I may mention that the boiler is 7in. × 2½in.—E. Nunn.

[46554.]—**Plumbing.**—To Mr. P. J. Davies.—I want to make an underground brick cistern, lined with lead, for the storage of about 200 gallons of benzoline outside of building, with pipe attached to a beer-engine inside of shop for retailing. Being only an amateur at soldering, I would like some instructions as to the easiest way of making the joints; if round or square cistern is preferable, weight of lead, iron or lead pipe, and the way to proceed to make a good sound job? If not capable of doing it myself, I have a friend, a plumber, who takes great interest in your invaluable articles.—Oilman.

[46555.]—**Induction Coil.**—I have a large coil of the following dimensions:—Tube (ebonite), 20in. long, 2¼in. bore, ¼in. thick; primary, three layers of cotton cd., No. 10 cop. wire, length of core, 18in., length of secondary reel, 13in., all ebonite, divided by ebonite discs into 120 divisions, which are filled with between 6lb. and 7lb. of silk-covered wire, 2lb. of No. 40 in centre discs, and over 2lb. of 36 at each end. Primary and secondary have both been steeped in paraffin; armature on spring, 1in. dia., 1in. long; contact on spring is half between tension-screw and centre of armature. With five small Grove cells I get the following results: Thick spark like flame over 1in.; broken or divided sparks, 4in.; occasionally thick spark goes across 5in., but when I tighten the tension-screw on spring, so that the magnetism of core cannot draw it away, then push it regularly and slowly away with my thumb, I get nearly continuous sparks 5in., and occasionally a spark goes 6in. Now it occurs to me that when it gives 6in. sparks sometimes, that it should give them always. Is that so? Do coils sold as 6in. spark coils give that length of spark occasionally or continuously? If so, where is the fault in my one? I have tried weaker spring with same result. Are these results good for a coil of that size and construction? When sparks are not going across at 5in. and 6in., there is a constant brush discharge.—J. R., Dumfries.

THE "ENGLISH MECHANIC" AND ITS FRIENDS.

Some of our readers, perhaps, never pay much heed to our little notice at the head of this column just at the ending or beginning of a new volume. Many do, however, we are happy to say, and to their efforts, in a great degree, the constant increase in the influence and circulation of "ours" is due. Mr. J. A. Brashear, of Pittsburg, whose valuable letters are familiar to our readers, writes us as follows:—"I write to send you the list of subscribers to English Mechanic for the coming year that I have obtained. As they are mostly scattered over the country, I have not all their money yet, but send you their names, so we will not be late, and will send postal order for them all next week. I will be personally responsible for all. I have more than half of the money, but prefer to send it all at once. I was rather late in commencing, owing to being so busy. There are ten altogether. There are a number of others who will send their own names, whom I have written to, so you see I have been at work for the benefit, not only of you and the journal, but for the benefit of *those who are fortunate enough to get the paper*." Our best thanks are tendered to Mr. Brashear, and our best wishes for a few thousand more readers—each to do his best to send us ten additional subscribers for the volume just commenced.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

GOOD FRIDAY.

The English Mechanic next week will have to go to press some hours earlier than usual, and all *advertisements* for the *next issue* must reach the office by 5 o'clock on TUESDAY, April 4.

The following are the initials, &c., of letters to hand up to Wednesday evening, March 29, and unacknowledged elsewhere:—

J. K. Rutter.—J. H. Harvey.—J. J. Vanstone.—O. H. Cussen and Son.—R. H. Blyth.—J. Munden.—Prof. Cavalier.—Lurgan Mechanics' Institute.—J. H. Huxley.—Vitreus.—Beta.—W. Holmes.—Anxious.—West Yorkshire.—Ouvrier.—Buttershaw.—Elecho.—Plodder.—Metallurgy.—F. Cox.—F. C. S.—Elephant Bill.—W. J. Pollitt.—C. M. T.—W. H. Richmond, Jun.—P. J. Farrelly.—Centaur.—E. B. Fennessy.—J. C. King.—W. H. S.—Crutch.—W. Haines.—D.—Fellow Workman.—F. C. Putley.—C. Cutler.—F. C.—Orderic Vital.—V. Broughton.—Hebe.—R. T. B.—E. Hardcastle.—Summit of England.—F. W. G.

Thos. Neilson. (The variation at Greenwich for this year is 18°20′ W.; in 1816 it was 24°30′ W., the maximum, and in 1976 it will be 0. In 1657 it was 0, so that from true north to extreme west and back to true north will occupy about 320 years, when the same cycle will occur on the E. side of the pole.)—Index. (See pp. 141, 176, last volume.)—F. Nunns. (See p. 237, No. 844; p. 633, No. 789. It is really an old method improved. No injury to the original; copies keep for years.)—A. H. C. (No book on such a subject. See p. 406, No. 823. Any dealer in paint will supply suitable preparations. We think you will find one in Leith.)—Blowpipe. (See the indices of recent volumes—the last for instance.)—T. Hendrey G. Brown. (You do not give the diameter of cylinder. You want to know the proportionate sizes of parts, we presume. 2. Of W. Love, Argyll-street, Glasgow, price 4l.)—Intending Purchaser. (We believe we answered you some weeks ago. It is no part of our province to insert queries asking which is the best machine in the market. Write to some of the Leicester makers, and you will probably obtain a reply.)—A. S. R. (Nothing novel in the principle, and you omit details. How do you propose to work, electrically or mechanically, and by what means? On p. 23 we gave a brief description of such a system, which has been fully worked out. Five minutes' conversation with a lineman would give you an idea of the difficulties.)—W. B. (12s. 6d. post free, bound in cloth.)—Mac. (Rubber solution is the only thing; but it would need securing with wires as well as binding round with tape. Looking at the risk, it is better to have a new one.)—H. Stull. (Apply to the Registrar of the Pharmaceutical Society, 17, Bloomsbury-square, for the pamphlet giving particulars of the examinations.)—E. Baker. (There are many subjects that would bear repeating; but we cannot repeat articles on magic-lantern making at present. See Nos. 605, 608, and 611, in Vol. XXIV.)—H. Marshall. (Can you not send us a description of the plate? It is lettered, and we presume a description is available.)—Pragmatical. (So small a machine is practically useless, though with suitable arrangement it might be made to cause one incandescent lamp to glow, and to produce a feeble arc.)—Novice. (Several advertised. We believe that referred to is Griscom's motor. It is expensive as compared to steam power. Read up recent back numbers, and especially consult p. 356, No. 743.)—Heraclitus. (You can do nothing better than expose the matting to the sunshine.)—Henry Walker. (Use large bichromates, say, a couple of half-gallon jars. Two plates of carbon, one of zinc, placed in saturated solution of bichromate of potash, to which has been added about a tenth of its bulk of sulphuric acid. When the battery fails move the zinc up and down, and subsequently add more acid. See p. 65, No. 731.)—J. R. C., Rock Ferry. (Purely a matter of taste.)—Collodion. (Do you not see that the very fact you mention is a proof that the size, within certain limits, is immaterial? All that is needed is that the wires shall be of soft iron and made up into bundles as round as possible. The actual difference in size in the case cited is ·35 of a millimetre. The length has nothing to do with the matter. Nos. 16 to 22 will do for any length.)—Jno. Browne. (If your connections are properly made, it ought not to "flicker," though we scarcely understand what you mean by the term. No doubt it fluctuates. You will not be able to prevent that.)—Jumbo. (To what do you refer?)—J. H. B. (Yes; a battery will convert it into a motor; but as a generator it would need power to cause the armature to revolve.)—Battery. (Use dilute sulphuric acid, not common salt. It is probably due to crystals forming in the substance of the porous pot and disintegrating it. You should take pot out and soak in water when the battery is out of action. See the indices for many references.)—C. W. Shute. (See p. 630, No. 728, and many other places in back numbers. A series of practical notes on batteries will be found in Vols. XXVIII. and XXIX., fully illustrated. 2. Scour the zinc quite clean by washing in soda solution and rubbing with sand. Dip in a weak solution of sulphuric acid and rub mercury on with a wisp of tow.)—Starlight. (See p. 192, No. 736, for a simple galvanometer; p. 129, No. 707; p. 153, No. 708; or p. 298, No. 610.)—Vega C. (Nothing less than a 6in. in the best atmosphere; probably not less than 7in. Five can be seen with 4in., but the others are only to be picked up by the finest large instruments. You should see the Debilissima with your telescope; but why not look through your back numbers, where all your questions are answered? You should procure Webb's "Celestial Objects." 2. It entirely depends on the experiments which is "best" battery. For the electric light, there is nothing better than the Bunsen; but if you want it only for a few minutes, the bichromate is to be preferred. You will want about 30 quarts; but see Prof. Ayrton's remarks, p. 4.)—C. M. R. (The best way is to get hold of a good textbook, such as Thompson's or Sprague's, if you really wish to study the principles. For many instructions in making and working apparatus, see back volumes.)—A Young Beginner. (See previous answer; or, as you want experiments, get Tyndall's book, which Stanley, Railway-approach, London-bridge, sells, with a collection of apparatus suited to it.)—A Three Years' Subscriber. (See two previous answers. The books you name deal with principles. Several machines of the kind fully described in back numbers. For instance, p. 470, No. 826.)—Ayrshire Lad. (Have you read the contribution on p. 426, No. 850? One lens.)—Scotchman. (About 18s. a week, according to age. Two or three years. Apply to foreman of shed. Not much choice as to line, and most have a number of boys waiting for promotion.)—G. C. M. Hall. (Not yet, we believe. Of the Queen's printers, East Harding-street, E.C.)—James Withers, Jr. (It will certainly be a difficult matter, for the reasons stated: but still you might find some one willing to take you for the one year, and then as an improver. Try the small shops, where they do general repairs. You will learn more in them.)—W. H. Binns. (Do you mean for pictures or cuttings from papers? If the latter, see pp. 153, 178, 203, 278.)—J. M. (Bury them in an iron box containing bone-dust, burnt leather, parings of horse's hoofs, or animal charcoal alone, and keep at a red heat for one or two hours, according to size; then turn out into water.)—Pliant. (Mix the rubber with sulphur in quantity according to the purpose, and then submit to steam heat in a vulcaniser.)—John. (See p. 210, No. 763. Use emery and oil, and run the blades backwards.)—Yoshi. (Described in No. 819, p. 396.)—H. Y. Powell. (We can only repeat our previous answer. We have no space to spare for such queries. See review on p. 582. The theories there mentioned are based on observed facts, and if you have any facts to bring in opposition to them, we might find space for them, but not for the fact that you "feel misgivings" You say "it seems improbable" that the entire globe weighs "more than twice that of granite," but you do not tell us what is the weight of a cubic foot of granite 20 miles beneath the surface. As to the other query, we say that the error is slight compared with the enormous difficulty of assigning any distance at all, and ask again, What has it to do with eclipses or the periods of comets? You have read your elementary books to little purpose.)—

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

◆

FRIDAY, APRIL 7, 1882.

ELECTRIC INCANDESCENT LAMPS.

JUDGING from the numbers of incandescent lamps which are now made every week, it is evident there must either be a very great demand for them or they must be very short-lived, for, if rumour is to be credited, one factory alone is turning them out at the rate of several thousands a week. There are at present five competing patterns, which differ from one another only in details, though some of them are very important, while others are mere matters of choice. From time to time we have given particulars of the various patents which have been taken out in connection with the "bridges" or threads of carbon which form the incandescent medium, and the method of preparing which seems to be the only real point of novelty in connection with the lamps. The early experimenters speedily discovered that even with a so-called perfect vacuum the carbon filament rapidly gave out, owing to the gases occluded in the pores of the carbon, and whilst some sought for special fibres, others endeavoured to so prepare the better-known materials as to overcome this difficulty. Hence, while Edison has, according to rumour, scoured the world and settled upon bamboo fibre, others have contented themselves with more easily-obtained materials, and have endeavoured to prepare what is needed by treating ordinary substances in such a manner as to render them practically homogeneous. Without attempting to give the dimensions of the outer shells of the lamps, which are really of no particular moment, it will suffice to say that they all consist of oval or globular glass envelopes, with more or less elongated stems, and a tubulure at the other end which is left for connecting with the vacuum-pump. The carbon thread, mounted with its wires in the stem-block, is passed into the shell and hermetically sealed by melting the glass around it, and the "lamp" is then placed in the vacuum-pump and submitted to the special treatment which the rival inventors or patentees favour. In Edison's case the thread is raised by degrees to a high state of incandescence while in the "pump," cooling being allowed after each passage of the current. By this means the occluded gases are believed to be eliminated, and certainly the fibres are submitted to a greater trial than they will experience in their future life as lamps. Of course, many of them fail, but the process secures the survival of the fittest, for it is only those which stand the test that are finally sealed up as practically perfect. Other inventors prefer to submit their carbon threads to a high heat in the presence of hydrocarbons, by which means they fill up the pores of the fibre with carbonaceous matter, and make the threads nearly or, it may be, perfectly homogeneous. In any case the final exhaustion is carried as far as possible before the lamp is sealed and passed as ready for use. At the Crystal Palace five different patterns are shown: the Swan (the earliest), Edison's, Maxim's, Lane-Fox's, and the British, and in appearance there is little to choose between them. The real test of superiority is, of course, durability, and of that we have no particulars, save that while at first the life of the lamps was reckoned only in hundreds of hours, it is now reckoned by thousands. Just as in the arc lights, the positive carbon wastes more rapidly than the negative, so in the incandescent threads it is found that there is a transference of carbon from one end of the bridge to the other, and although in the newer devices this defect has been partially remedied by making the thread thicker at the negative end than at the positive, it is obvious that it practically determines the life of the thread, which sooner or later must give out. We hear of threads lasting 4,000 hours, and even longer, which, for practical purposes, means a year of lighting without requiring new lamps; but we imagine that in making an estimate it would be preferable to reckon the life of a lamp at 2,000 hours, which will probably cover contingencies. Besides the carbon thread itself, an important point is the means of connecting it with the wires, and here we find the chief divergence between the different systems; for while Edison prefers, or, at any rate, uses platinum junctions coated with copper, Lane-Fox coats the ends of his filaments with platinum, and dips them into globules of mercury. Maxim's, Swan's, and the British, all use platinum connections slightly varied. For the filament itself, Lane-Fox uses the fibre familiar to housekeepers as bass-broom, the British Company use cocoa-nut fibre, Maxim and Swan prefer paper, cardboard, or cotton, and Edison, as mentioned above, bamboo. The latter, in fact, professes to have tried all sorts of substances, and to have found in certain species of bamboo just the kind of fibre he requires, both for uniformity of substance and for the facility with which it lends itself to the necessary manipulations. On page 462, Vol. XXXIV., we illustrated and described Edison's latest method of making and arranging incandescent lamps, and it will be sufficient to say here that the bamboo canes are first cut into lengths, then split through the centre, and each half further divided into three. The hard flinty shell is then removed, and the pieces planed down to uniform thickness, when they are placed between metal blocks and subjected to forcible compression, leaving the press as fine threads of bamboo with thick ends. They are then ready for the most important stage in their preparation. This consists in bending them to the required shape by forcing them into grooves in a nickel plate, which is then covered by another plate of the same metal, and the two being clamped tightly together, are raised to a red heat in a furnace. The filaments are thus carbonised, and are attached to the platinum wires in the glass foot or stopper of the lamp (see p. 462, Vol. XXXIV.) by a copper film deposited by electrolysis. The foot being blown into the lamp, the latter is put in the pump, and while the exhaustion is being carried on a current is sent through the bridge of bamboo fibre, which is allowed to cool down several times, while it is raised by degrees to the highest state of incandescence. It is believed that by this means the occluded gases are completely eliminated, but other researches have shown that it is extremely doubtful whether any natural fibre or other form of carbon can be altogether freed from hydrogen, and Mr. Edison acknowledges that, in the present state of the art, it is impossible to construct a lamp which shall have an indefinite duration so far as the carbon thread is concerned. The vacuum in the lamps is produced with ease by means of a modification of Sprengel's pump, a tube being left projecting from the top of the shell, which is connected to the pump-tube. The required vacuum having been produced, the tube is sealed near the joint with the pump, and the lamp being thus separated, the final closure of the shell is made in the form of a bulb fused on the end of the tube, which in the finished state is little more than a projection from the surface of the shell. The lamps hitherto shown by Edison are pear-shaped, but other forms have been made, that most liked by the inventor being a cylinder with rounded ends. In all, however, the finishing or connecting terminal is a screwed piece in which the platinum wires are secured respectively to a screw and a cone in thin brass (the latest are of thin copper), which are insulated from each other by plaster of Paris. The socket, which has the "lead" and return similarly connected to a cone and a female screw, thus makes perfect metallic contact with the lamp as soon as the latter is screwed home. The details of this arrangement have been modified in some specimens, but in principle they are the same. The large-sized lamps have a resistance when hot, of 130 or 140 ohms; the smaller or 8-candle half-lamps, as they are termed, have a resistance of about 80 ohms.

The description above given of the manufacture of the carbon filaments applies with some alteration of detail to all the lamps mentioned; but all the inventors have not been so successful in devising an easy means of securing perfect connection with the main lead and return. Edison uses a filament with a plain bend, Maxim bends it twice on itself so that it represents the letter M, and Swan, as we have previously shown, uses either plain loops or coils. The Maxim lamp is fitted into a socket containing two insulated springs as terminals to the conducting wires, so that perfect contact is maintained by their pressure. These details, which are really of considerable importance, will no doubt be improved; but at present the plan adopted by Mr. Edison is by a long way the most simple as well as efficient. The arrangements for turning out a lamp are practically the same in principle and can be readily understood. The tap, which resembles nothing so much as a gas-tap, in one position is in contact with the lead, lamp, and return, and in the other with only the lead and return, so that no current passes through the lamp when the tap is turned sufficiently to break the circuit with the lamp. Edison uses a split cone, which is, by means of a quick screw-thread on the tap, drawn into connection with two metal blocks, to which the wires are secured. In these simpler arrangements it will be understood that the light given by the lamp depends on the machine generating the current; there is no means of reducing it by turning the tap, which, as before explained, either makes or breaks circuit; but amongst Mr. Edison's devices there is one by means of which the amount of light can be regulated within certain limits. That he accomplishes by means of a rheostat composed of a number of vertical rods of carbon, resembling an elongated lantern-pinion. By turning the base of the box the resistance offered to the passage of the current can be increased or diminished, and within those limits the intensity of the incandescence of the carbon filament can be regulated. The display of incandescent lamps at the Crystal Palace, the steadiness which is their peculiar property, as compared with the arc lights, and the facility with which they lend themselves to all purposes of domestic lighting, have made them the popular favourites; and, we understand, that one factory is selling them at the rate of several thousands a week. The duration of any of these lamps is determined practically by the durability of the carbon filament, though occasionally the glass envelope fractures; but the problem to be solved is the possibility of so preparing the threads and so shaping them that they may have an indefinite life, for it is

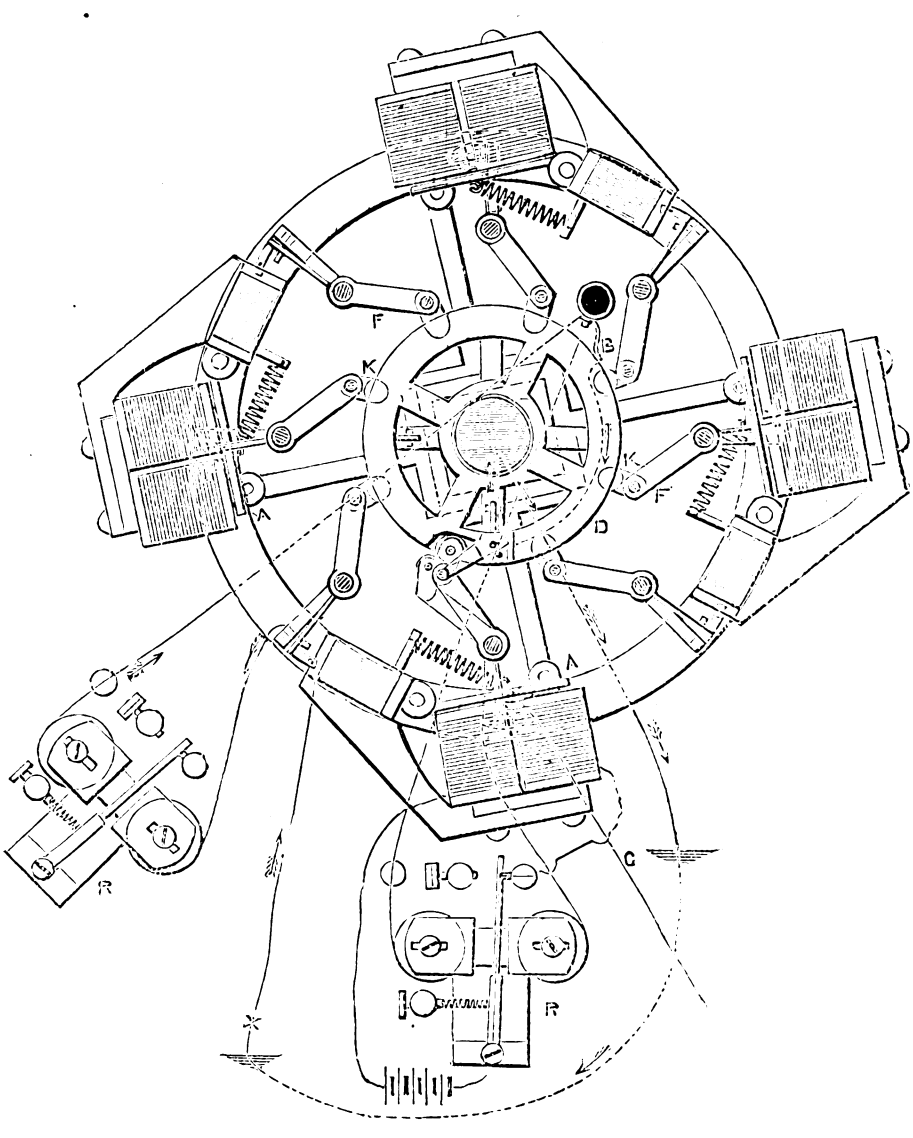
VOL. XXXV.—NO. 889.

clear that if any serious expense is incurred in replacing broken or worn-out lamps, the incandescent system, already more expensive, from the photometric point of view, than the arc lights, will be severely handicapped. That many inventors are turning their attention to the production of superior carbons, our columns testify, and probably in some such direction as that taken by Mr. Crookes (see p. 247, Vol. XXXIV.), the greatest measure of success will be attained.

TELEPHONE EXCHANGE APPARATUS.

THE Telephone Exchanges have scarcely done more than elaborate, and make fairly complete, the systems of switching for use in central stations, before an ingenious inventor comes forward and provides an arrrangement by which any subscriber can connect his telephone with that of any other member of the exchange by means of an automatic instrument in the central office, thus dispensing with the services of an attendant. This apparatus has been patented by Mr. T. A. Connolly, of Washington, and has been recently patented in this country as well as elsewhere. To give a full idea of the various ways in which the invention can be worked would occupy more space than we can spare, but with the assistance of the annexed engraving we shall probably be enabled to render the principal features clear. The apparatus at the central station is of an upright cylindrical form carried on a base with the binding posts to which the various line wires are attached. The engraving is a horizontal section, showing, as if they were on one plane, the electro-magnets, the pivoted armatures of which are connected to escapements or ratchet and pawl devices, for converting the motions of the armatures into the rotary motion of a ratchet wheel. The magnets are really in separate planes or tiers as we may say; they receive current from the central battery, and normally the circuits are open. The closing of these circuits is effected by means of relays R in the normal circuits of the subscribers' or members' lines; these relays are responsive to the impulses transmitted from the subscribers' stations, hence each pulsation of an armature A is in keeping or correspondence with that of its relay. These relays are polarised, and preferably of the form known as "Siemens'," and are adapted to close the circuit of the magnets when the current which energises the said relay is passing in one direction. The current in the reverse direction may be utilised for signalling purposes without effecting any operation of the central machine. The magnets and their ratchet appliances are employed to effect the rotation of the rings or wheels D, one of which is allotted to each line. In addition to a ring each line possesses a "contact bar" or frame F; these frames are pivoted either inside or outside the ring, or outside of the wheel; they are arranged at regular intervals around the rings, and are parallel with the axis thereof. Each bar traverses the whole series of rings, so that all the rings have a similar relation to each and every frame. A connection of any two lines is effected through the ring of the operating or calling line and the contact bar or frame of the called line; for this purpose each ring is furnished with a coupling or connecting device, which in the arrangement under consideration consists of a "tripper" or toggle lever; this lever, as a ring D rotates, comes in contact with the several frames, and rotates the same on their shafts or bearings; at the same time the tripper or toggle, which is normally tangential or inclined with reference to the periphery of the ring, assumes a different position, that is to say, it straightens out, and if then the movement of the ring is discontinued, the tripper and frame remain in their conjointly assumed positions. The object of moving the frame is to isolate it, so that when engaged by a line no other line can obtain connection with it; for this purpose the conditions are such that in its normal position the outer end or head of the tripper does not project sufficiently far beyond the ring or wheel to touch the frame or contact bar when moved or turned by an engaged tripper or toggle.

A line when not in use, or when employed in effecting connection with another, completes its circuit to earth, or to a common ground or return through its tripper or toggle. When engagement is made with a line, this ground or earth connection is broken by the movement of the tripper under the toggle action of a frame or contact bar, and the circuit is completed through the line in which the frame is located. Speaking more specifically, each ring or wheel consists of two plates or rings of metal separated by an insulating filling; the lower plate is in constant contact with the frame of the central machine which communicates with earth, or return, either through supporting rollers if a hollow ring is used, or through a central shaft if a wheel with spokes is employed.



The tripper or toggle lever consists of a finger pivoted to the upper plate of the ring or wheel, and formed with a shoulder abutting against a stop, which limits its movement in one direction, and against which the tripper is held in impingement when not engaging with a contact frame by an easily yielding spring. A spring tail piece or continuation of the tripper or toggle impinges against a bent metal pin, stud, or block extending upward from the lower plate of the wheel or ring, and travels thereon during a portion of the movement of the tripper on its pivot. Thus the operating line which leads into the upper plate and thence to the tripper or toggle makes ground through the said pin, stud, or block, until in engaging with a contact frame such ground connection or contact is broken by the tail-piece leaving the same, when the circuit is diverted into the contact frame to be thence led to the line thereof. As above stated, the tripper or toggle lies normally in an oblique or tangential position, as shown; its outer end is formed with a slight concavity or recess, by which a contact frame in its path is caught and held in effecting and maintaining engagement therewith. As the tripper passes each unoccupied contact frame, momentary engagement and conjoint movement ensue, and the diversion of the circuit from central ground to the line of the engaged frame follows. The circuit or contact is made with the ring from the line thereof by means of a brush or rubber B in the path of the same line insulated from the main frame. A wire leading from the said brush connects with a binding post or cup to which is led a return wire from the relay of the same line. The main line wire G from a station leads to connections in the central machine, thence to the relay, and from the relay by the return wire to the binding post. This circuitous path is provided in order that the relay of a called or passive line may be cut out, so as to reduce resistance, but principally to prevent such relay from being operated by the current of the operating line. Thus when a contact frame is engaged, the circuit with its line is made directly from the outer segment to the line without passing through the relay, the latter being in the branch circuit connected permanently with the inner or shorter segment. It has been explained that when a contact frame is swung out to its limit and engaged by a toggle or tripper, the toggle or tripper of another line will pass by without coming into contact therewith, thus preventing disturbance of the communication through the frame of the called line. Engagement, however, with the frame of an operating line is not thus provided against, but such provision is necessary to prevent the operating line from being broken. For this purpose each contact frame is furnished with an arm K supporting an anti-friction roller, which rides on the periphery of the insulated filling of the ring of the same line. A cam recess in the said filling adjacent to the tripper receives the said roller when the ring is home, but as the latter begins to move the roller is pressed outward to the periphery of the insulated filling. By this operation the contact frame of the operating line is swung on its pivotal points sufficiently to avoid the contact of the passing trippers, but not far enough to break the circuit through the segments. It is, therefore, only when a line is at home that its contact frame can be caught. The term "home" is used to indicate the normal position of the tripper, that is to say, the position it occupies when it coincides with the contact-frame of the line to which it belongs or pertains. A contact frame, however, is not to be pushed out by its own line tripper, otherwise the tripper of another line could not engage it. To avoid such a difficulty each contact-bar is notched or recessed at a point opposite or on the plane of its line tripper, so that when the latter is home it projects into the notch or recess and does not touch the bar.

The operations of the central line connecting apparatus are responsive to electrical impulses sent over the lines from the local or subscribers' stations. These impulses are produced by the intermittent closing of a normally open battery circuit which correspondingly closes the relay at the central machine, and thus brings into action the power whereby the mechanical switching operations are performed. Each local or subscriber's station for this purpose is furnished with an independent battery or generator which has one pole grounded or in connection with a return common to all the lines. The local subscribers' station apparatus for giving control of the central devices pertaining to a given line are for convenience enclosed in a case to which are connected the necessary devices pertaining to the usual telephonic transmitter and receiver. From the battery the line and ground conductors lead to a reversing key, which is carried by a toothed disc or wheel, whose teeth correspond in number with the number of impulses necessary to effect a complete revolution at the central machine of the carrier of a contact making finger or tripper. The said disc or wheel is caused to rotate by suitable clockwork mechanism, and its teeth successively pass a contact-making spring or arm which completes or closes the open line circuit, and sends an impulse through.

The disc or wheel is covered by a dial, upon which the several lines of the exchange are indicated by suitable numbers or letters at regular intervals completing the circle. Holes are bored through this dial in coincidence with the said numbers or letters for the reception of a transferable plug. A stud on the disc or wheel comes in contact with this pin on open circuit, and arrests the movement of the wheel at any given number opposite the pin, whereupon the operations of the devices pertaining to the operating line at the central apparatus cease, the operating line being then in coincidence and circuit with the line at whose number or letter the pin is placed.

To provide for a reversal of the current after such circuiting has been effected, the line and ground wires from the local station battery lead to the reversing key through brushes touching insulated collars on the disc-shaft, which collars communicate with the terminals or contact points of the reversing key. The latter has an elongated arm, which, as the disc comes to a stop, touches and bears against the pin when the same is at any but its home position. Under such conditions the direction of the current while the disc is rotating is such as will effect the operation of the relay, but when the arm of the reversing key strikes the pin the direction of the current is reversed. The hole for the reception of the pin when at home, that is, at the number on the disc or dial of the station to which it belongs, is out of the circle of the other holes. Hence when the disc arrives home the arm of the reversing key does not strike the pin, so that no reversal takes place. The object of the reversal is to provide for calling a distant station by an operating line without operating the relay of the latter. This calling is performed under the reversed currents by means of a circuit-closing key or push in a branch or shunt line which is normally open. Now when a line is at "home" and a pin in a "home" position it is in a condition to be called, but at no other time is it in such condition. Then when a calling current is received, the relay of the called line is cut out, as previously explained, so that the calling current cannot affect it as it otherwise would, the direction being suited to such operation. Having been called, a call is returned from a distant station by simply pressing the push button at the latter. The return call current is then in the normal direction, that is to say, in the direction under which the called line relay would operate were it in circuit, but it is the reverse direction relatively to the relay of the calling line, or in the same direction as the calling current of the latter, and hence has no effect on the relay. This automatic method of reversing the current is desirable, so as to obviate the possibility of mistake in making and returning calls growing out of the necessity of calling up a line and returning a call, of having the currents in the same direction, notwithstanding the peculiar relations of the two lines, the one operating and the other passive. But for such automatic contrivance relieving the callers of the necessity of exercising selection in manipulating their calls, it would be necessary to provide an independent reversing key which the caller would have to shift after obtaining a line while the person called must leave it alone. In this case, if the caller were to accidentally or inadvertantly omit such shifting he would operate his relay, while if the called subscriber should shift his reversing key he would also operate the caller's relay, and so destroy the conditions obtained at the central apparatus as well as the unison of the local indicators and the central devices. The machine is practically a combination of devices through which electrical circuits are determined and produced, and such circuits may be used either for telephonic or telegraphic purposes. The only requirement when the machine is used for telegraphic purposes is that the signals shall be sent by currents running in one direction only, so that such signals shall not affect the polarised relays.

WATCH-CLEANING AND REPAIRING.

By "A Fellow-Workman."

(*Continued from page* 74.)

FIG. 30 is the clickwire fitted in the pinvice so that you can see how the pivot is got. B is the *dog*, and A is the tail of click, which should rest against the outside of the countersink in fuse-wheel. The square will sometimes get worn so small that a key soon gets worn out.

FIG. 30.

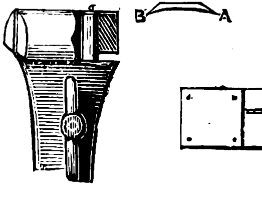


FIG. 31.

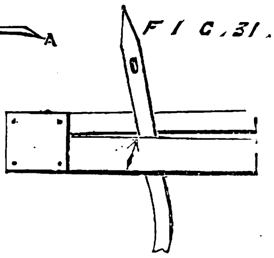

FIG. 33.

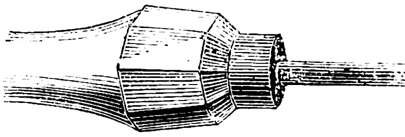

FIG. 32.

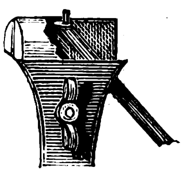

FIG. 34.

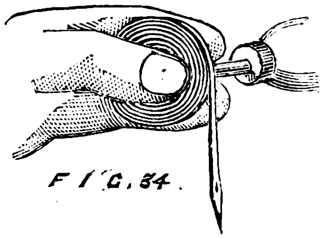

FIG. 35.

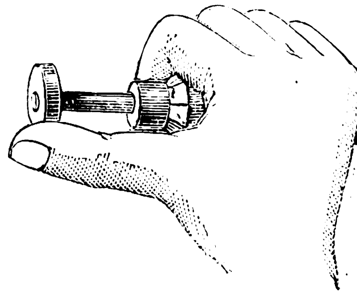


The easiest way that I know of to repair it is to file it up square, fit on the pipe of a watch-key, soft solder it on; put on a brass rose to protect pivot while you fill up square. To get a square you must take your pinvice as a guide.

Barrel.—The holes of the barrel in old watches sometimes get worn; you can make them smaller by punching round the hole on the inside, and then rimer them out with a round rimer. If you have a proper turn, you can fit a new bush.

Mainspring.—When a mainspring breaks, the barrel reverses; this generally unhooks the chain, which is almost a sure sign. If it breaks on the outside coil, the watch will sometimes go for two or three hours. This will sometimes deceive you: when a watch is brought to be repaired, you will think it wants cleaning. You can generally find out, by poking the barrel to see what strength the spring has got. Select a mainspring as near like the old one as you can. Some jobbers tell the strength by laying the spring on the first and second finger, and pressing their thumb on the middle, having the old one in one hand and the new one in the other. Then they reverse them. A gauge is easily made by two pieces of brass being riveted and soldered together (Fig. 31). First get width with your callipers, then thickness with Fig. 31. Having selected your spring, get length by old one; soften the outside end about an inch, file it, and make it weaker. Now taper the end and punch for rivet (see Fig. 31); now file up a piece of soft steel wire, size of hole in barrel; cut off inside after allowing for rivet; then place it in your pinvice and file up as shown (Fig. 32). Chamfer the inside of the hole in the spring; now place rivet in the vice. Put the spring on it; see that you have got it the right way; now with a small hammer keep tapping round the outside of the rivet. Don't touch the middle. As soon as it gets oval, file it flat. In this way you will make a good strong rivet. Leave it a *little* oval at the finish as a support to the outside; now cut off about the length required for the barrel—you can measure from the outside; file it level and polish the end. You can buy a mainspring winder for about 1s. 6d., but you can make a simple one (Fig. 33). Place the spring between your fingers, as shown in Fig. 34; put the winder between your fingers; when you have got it wound up, place your thumb upon it as shown (Fig. 35); pick up your barrel and put in spring. If you can't do it this way, you can do it by putting the outside end in its place in the barrel, and work it in, coil after coil; but this way will sometimes break highly-tempered springs.

(*To be continued.*

THE APPLICATIONS OF ELECTRICITY.*

I WILL endeavour, in two lectures, to review the principal applications of electricity, which you have seen working in the recent remarkable exhibition of the Palais d'Industrie. From a practical point of view we may divide electricity in two chapters: statical electricity, which is produced by friction; and dynamical electricity, which is obobtained by chemical or by magnetical action. Statical electricity has so very few applications that I may almost pass it over in silence. I will only remind you that the old-fashioned frictional machines are now superseded by dielectric machines, such as Holtz's and Carre's. At the exhibition you may have noticed machines with several dozen plates turning simultaneously, and giving very powerful effects.

We will at once turn our attention to voltaic or dynamical electricity, which has received an endless number of applications, among the most important of which are telegraphy, telephony, and galvanoplasty, which will form the subject of my first lecture.

The source of electricity generally used in these branches of the science is chemical action. You remember that Volta's pile was composed of rounds of copper, wet cloth, and zinc, always piled up in the same order; a short time afterwards he arranged plates of copper and zinc is glass cells, containing water acidulated with sulphuric acid, and connecting the copper of one cell to the zinc of the other by a wire. When the two extremities of such an arrangement are put into communication by a conductor such as a copper wire, a current of electricity flows from the copper or positive pole to the zinc or negative pole. You will not have omitted to notice the interesting collection of these piles and batteries in the retrospective part of the exhibition. The strength of these batteries very soon falls, on account of the hydrogen which goes to the copper plate. In order to avoid this, Daniell placed the copper in a solution of sulphate of copper contained in a porous cell. By this means the hydrogen could not reach the copper; but reduced the metallic solution, and precipitated copper on the positive copper pole. This battery, and various modifications of it, are much employed where constancy is required. Bunsen absorbed the hydrogen by nitric acid, and formed a stronger, but less constant, battery.

---

* Lectures delivered by C. Detaille, at the Palais du Trocadéro, Paris.

In the Leclanché battery the carbon is inclosed in a mixture of carbon and manganese dioxide. In the new form of the cell, of which we have here a battery constructed by M. Barbier, the porous cell is done away with, and replaced by plates of the agglomerated mixture of carbon and black oxide of manganese on each side of the positive plate.

Having reviewed the chief kinds of batteries, let us now examine and apply the properties of the electric current. We have here a long strip of steel, magnetised and freely suspended by a silk thread. When left to itself it takes a fixed direction, and points in the magnetic meridian—*i.e*, nearly north and south. Let us now take this wire in which the current flows, and approach it to the suspended needle; you at once observe a deflection, either to the right or to the left, according to the sense of the current. This simple experiment at once leads us to Wheatstone's single-needle telegraph, which is not used in France, but is much employed in England. It simply consists of a magnetic needle, which may be deflected either to the right or to the left by a current flowing in a coil of wire. The alphabet is spelt out by the deflections of this needle. Thus, if we wish to send the letter F we send the needle twice to the left, once to the right, and once again to the left; for the letter T we send it once to the right, and so forth. This telegraph is very simple, but requires much practice for sending and receiving quickly. Another very interesting application of the deflection of a needle by a current is Sir William Thomson's reflecting galvanometer. The needle is suspended horizontally and inclosed in the bobbins, through which the current flows; a small mirror is attached to it; a beam of light thrown upon this and received upon a screen makes the slightest deflections visible; messages are thus sent by deflecting the spot of light to the right or to the left; the same alphabet is made use of as with the single-needle telegraph. This instrument is used on the Transatlantic cable. It requires very experienced clerks to read the messages on account of the irregular movements of the light; this is very fatiguing work for the eyes, and much impairs the sight. Sir William Thomson has recently invented a very delicate instrument named the siphon-recorder, which leaves a permanent record of the message, and thus supersedes the reflecting galvanometer. It consists of a coil of wire placed between the poles of a powerful magnet. It is deflected by the current either one way or the other, and communicates this movement to a siphon which spurts ink on to a moving strip of paper. The siphon makes a series of zigzags which are above or below the middle line, and vary in number according to the letter which they represent. The siphon is made of a very thin glass tube only weighing a few grains, and the ink is forced through this capillary canal by means of statical electricity from a small machine.

(*To be continued.*)

MECHANICAL HARDENING AND MAGNETISM.

IRON and steel can, of course, be hardened by mechanical operations, such as hammering, drawing, and bending, as well as by the common thermal process. The influence of such treatment on their magnetic properties has been lately investigated by Herr Cheesman, in the laboratory of Prof. Kohlrausch. The research is described in a recent number of the *Annalen der Physik*.

The materials used were the English "silver steel" of commerce, in wires of 330mm. length, and of three different diameters (1mm., = about ·04in., 1·2mm., and 1·6mm.), as also in a few bars, and a long annealed iron wire, 1·6mm. in diameter. All the material was carefully annealed before use. Various degrees of hardness were imparted to the annealed wire by beating, bending, drawing through holes, and stretching, and their influence both on the permanent magnetism with strong magnetising forces, and also on the temporary and permanent magnetism with forces of various strength, was examined.

The magnetisation, in the case of strong forces, was done with permanent magnets, and the magnetism measured in the magnetometer. These experiments proved, in the case of iron wires hardened by hammering and stretching, that a greater specific magnetism was produced than in the soft state, the increase, in one case, amounting to nearly three-fourths of the original value. When the iron wires were drawn through a various number of holes, there was also, though not in a very regular way, an increase of the specific magnetism with the number of holes through which the wire was drawn. The difference between the wire drawn six times, and the soft wire, was about 60 per cent. Lastly, when iron wires were stretched with increasing weights, the value of the specific magnetism increased regularly with the hardening produced, this increase amounting to about 70 per cent. A cast-iron bar, 102mm. long and 7mm. diameter, showed as specific magnetism, in the soft state, 40·1, and after hammering and remagnetising, 44·1.

Similar experiments with similar steel wires yielded quite a different result. The soft steel wires showed a greater specific magnetism than the hard ones, and it was smaller the harder the wire. These experiments with iron and steel were frequently repeated, but always with the same result. Mechanically-hard iron seemed to be always capable of taking more magnetism than soft, while the reverse was the case with steel.

This behaviour of steel, however, is not universal; it is very materially influenced by dimension. A steel bar, 117mm. long, and 7mm. diameter, after being hardened by hammering, showed, in specific magnetism, an increase of about 33 per cent. A similar increase, after hardening, was observed in other steel bars of like dimensions. This phenomenon, occurring where the length is comparatively small in relation to the diameter, and its converse, in the opposite case was in agreement with facts observed some time ago by Herr Ruth, and attracted further investigation.

The experiments now showed distinctly how the magnetic moment of steel depends not only on the state of hardness, but also on the ratio of axes (a); below a certain value of a, the hard wire has greater moment than the soft one; and this value, at which the magnetic moment was independent of the hardness, was, in all those experiments, very near 41. Though iron was experimented with between similarly wide limits, no corresponding behaviour was observed.

The results, thus far, are summed up as follows:—"Using strong magnetising forces, within the limits of investigation, iron is capable of taking, in the mechanically hard state, more permanent magnetism than in the soft; on the other hand, the magnetic moment of a steel magnet in the mechanically hard state is greater or less than in the soft state, according as the ratio of axes is less or greater than a certain transition value."

In the further experiments, the question was considered, how far mechanical hardness presents a resistance to magnetising force; and for this purpose measurements were made both of the temporary and of the permanent magnetism from magnetic forces of various strength. Magnetisation was here done with a magnetising coil, and each time the author successively observed the indication of the magnetometer with open circuit, and that with closed circuit and the magnet in the coil; then the strength of the magnetising current was read off on a galvanometer, and lastly the indication of the magnetometer with open circuit and the magnet in the coil. The results of the measurements are given in tables and curves, and they teach the following:—

"Comparing together the curves corresponding to temporary magnetism, both of iron and of steel, it appears that the soft wires, for the same value of separating force, have a greater moment than the hard; hence, as was to be expected, mechanical hardness has an action of restraint on the rotating of the molecules. From the curves of the permanent specific magnetism of iron, the conclusion is to be drawn, that only with very small values of the separating forces is the moment of a hard iron magnet less than that of a soft one. In steel, on the other hand, the influence of dimensions appears; for in bars with a great ratio of axes, the specific magnetism, both for weak and strong forces, is greater in the soft than in the hard. In those bars, on the other hand, in which the ratio of axes is small, the harder of them, for all forces except the very weak, has the advantage."

These results correspond fully to the behaviour of bars hardened by heating, as observed by Herr Ruths and others.

"Though in magnetic relation," says the author in concluding, "the two kinds of hardness (the mechanical and the thermal) show many similarities, they present, in other relations, many differences, and seem to be quite different states. With regard to conductivity for electricity, e.g., this comes out most strikingly. The conduction resistance of drawn iron and steel wires has been given very differently by different observers. some have affirmed an increase of it, and others a decrease, with hardness; but in any case it changes very little. On the other hand, according to data by Barus, the specific conduction-resistance of steel is altered by heat-hardening nearly threefold. The differences in magnetic relation by no means correspond everywhere to this great difference.

"A comparison of the specific gravity of the wires hardened by the two methods with the corresponding magnetic moment, leads to the same result. By quenching, it is known, the specific gravity of steel is diminished, and it reaches its smallest value in the quenched state. According to Fromme's results, the specific gravity increases again in annealing, but the magnetism decreases, so that for a small ratio of axes, the smallest specific gravity would correspond to the greatest specific magnetism. The magnetism of a steel bar (with small ratio of axes), hardened by hammering, steadily increases, on the other hand, with the specific gravity, as I have often convinced myself by experiment.

"It may here be pointed out that the specific gravity appears generally not to be indicative as to the magnetic state. For even if other circumstances did not show this, it is not conceivable that the specific gravity of the steel bar, whose ratio of axes is great, should decrease through hammering.

"The verification of Ruths' affirmation of the dependence of the specific magnetism of steel on the ratio of axes, for mechanically hardened wires also, proves the importance of this point for the magnetic state. As to the behaviour of iron in this respect, the possibility is, of course, not excluded that a value of the ratio of axes exists, at which the moment is independent of the hardness; only, according to the experiments made, the value must be different from that for steel. With the present defective experiments as to this point, it may be difficult fully to explain these phenomena. I hope, however, shortly to investigate the behaviour of hard and soft iron with very large and very small ratios of axes, as also, generally, the dependence of a on the variables which determine it."

THE HIBERNATION OF ANIMALS.*

DON'T black bears sleep through the winter? questioned the writer of an attendant who was dealing out mid-day rations of bread and milk at the park. "That's the general impression," was the rejoinder, "but we have never noticed any attempt at hibernation here. Bears are unusually lively during the cold months, and demand their food as regularly as do the lions and other feline animals. I don't know that any observations of value on this question have ever been made on animals in confinement. I have had some experience with outside animals, and a great many go through what is called a winter's sleep; and in warm countries there is what might be called a summer sleep. Bears begin in the fall to look out for a soft nest; and if it's possible for them to eat more at one time than another they do it then, and when the cold weather sets in they are fat and in prime condition. According to some authorities, the fat produces the carbon that in some way tends to induce somnolency. The stomach of a bear at this time becomes empty, and naturally shrivels or draws into a very small space, and is rendered totally useless by a substance called 'tappen' that clogs it and the intestines; this is formed of pine leaves and other material that the animal takes from ants' nest and the trunks of trees in its search after honey. They lie asleep in this condition for about six months, generally snowed in; but you can tell the place, as the heat of the bear, what there is left, keeps an air hole up through the snow. The bear seems to live on its fat, the tappen preventing its two rapid consumption; and if you run across them during this time—even along in March just before they wake up—they are about as fat as when they went in. I have taken a slice of fat from a black bear six inches thick—regular blubber. I remember," continued the man, "one winter I was 'log hauling' in the western part of this State. We had our eyes on a big tree, and one morning, when it was about ten degrees below zero, I tackled it to warm up. I hammered away for about five hours at it and finally started her, and over she came—slowly at first, and then as if she was going right through The snow was nearly three feet deep, and as the tree struck it flew up for about twenty feet and half blinded me, and when I came to there was the biggest black bear I ever saw standing along side of me, looking about as mixed as I did. I had lost my axe, and the first move I made she started, and on taking a look I found that she had a nest in the trunk and had probably turned in for the winter.

---

* By C. F. Holder in *Forest and Stream.*

It was about twenty feet from the ground, and was built with moss, leaves, and all kinds of truck, and as warm and as snug as you please—a good place to spend a winter in."

The brown and polar bears have the same habit of lying up for the winter. An Eskimo informed Captain Lyon that in the first of the winter the pregnant bears are always fat and solitary. When a heavy fall of snow sets in the animal seeks some hollow place in which she can lie down, and remain quiet while the snow covers her. Sometimes she will wait until a quantity of snow has fallen and then digs herself a cave; at all events it seems necessary that she should be covered up by the snow. She now goes to sleep and does not wake until the spring sun is pretty high, when she brings forth two cubs. The cave by this time has become much larger by the effect of the animal's warmth and breadth, so that the cubs have room enough to move, and they acquire considerable strength by continually sucking. The dam at length becomes so thin and weak that it is with great difficulty she extricates herself, which she does when the sun is powerful enough to throw a strong glare through the snow which roofs the den. Then the family comes out, and will take anything that comes alone in the way of food. During the long sleep the temperature of the bear's blood is reduced to almost that of the surrounding air. The power of will over the muscles seems to be suspended, respiration is hardly noticeable, and most of the vital functions are at a complete standstill—the entire body sleeping, as it were. The male grizzly bear never hibernates. The young and the females, however, build nests, one of which measured ten feet high, five feet long, and six feet wide.

Bats are great winter sleepers, and in most of the known caves they can be found during the cold months clinging to the walls and to each other. During hibernation their respiration ceases almost entirely, and only the most careful use of a stethoscope can reveal it. The air that has surrounded numbers of them has been carefully examined, and not the slightest evidence found of its having been breathed; and, stranger yet, they can exist in this condition in gas, that, were they awake, would prove instantly fatal. A machine has been invented to examine these and other animals while in this condition. A delicate index records the slightest pulsation, while a thermometer shows the rise and fall of the temperature at every moment during the period; and by an arrangement of the wing, the circulation of the blood is recorded. A more delicate experiment can hardly be imagined, as a strong breath, a sneeze, or a footfall will cause the subject of the experiment to recover enough to respire several times; and the effect of this on the machine can be imagined when it is known that, though, while in this condition, they produce no effect upon the oxygen of the air about them, they consume when respiring more than four cubic inches of oxygen an hour.

The common marmot is a great underground sleeper. They build large storehouses, sometimes eight feet in diameter, and from the latter part of September to April they lie in them, and, like the bears, give birth to their young during this period.

The dormouse is a remarkable sleeper. Even in their ordinary sleep they can be taken from the nest and handled without waking them. Towards winter they acquire a great deal of fat, and stow away a vast amount of provision around about their nest, and then go to sleep within; but they rarely awake to use this food unless a very warm period comes around before the regular breaking up of cold weather.

The hedgehog is a sound winter sleeper, and has been the subject of an infinite number of experiments while in this condition. One experimentalist, believing that cold was the cause of their curious condition, surrounded one with a freezing mixture, and froze it to death. By increasing the cold about another that was already hibernating, it was made to wake up; and walked off.

If an animal is suddenly decapitated while in this hibernating condition, the action of the heart is not affected for some time, a second life seeming to outlive the one taken. An experiment has been made in which the brain of the sleeper was removed, and then the entire spinal cord, but for two hours hardly any change was noticeable upon the action of the heart; and a day after that organ contracted when touched by the operator.

The writer has the winter nest of a family of ants. A piece of fence rail was found beneath an old pile of boards and brought into a warm room for the sake of a rich fungus growing upon it, and several hours after the table and chairs were found to be covered with ants. Where they came from was a mystery, until the old rail was accidentally jarred and a number fell from it. A section was cut down through it, and the winter home of the tribe destroyed—probably the work of weeks, perhaps months. The interior of the wood was completely riddled by tunnels and passages, some being large and holding several hundred ants, while others contained only a few. In some of the interior passages the ants had not been affected by the heat, and were packed in great masses and evidently fast asleep; they soon recovered, however, and walked off slowly in different directions, as if wondering if an earthquake or spring had come.

A great number of insects go through a period of hibernation, especially spiders. The young of the latter are often covered by the parent; first, by course strings of silk, as if to hold them in place, and then by a white, silvery web worked over them, which forms probably a sure protection from wind and weather.

The writer has a cherry-stone in which is coiled up an insect, best know as the sowbug. A squirrel had probably eaten out the meat and opened the way, and in this snug retreat we found the little hibernater snugly rolled up, as is also its habit when alarmed. The mouth of the hole was stopped by black soil, but whether from accident or by the animal itself we could not tell.

Some fishes and reptiles are hibernaters. Frogs and toads sleep out the winter at the bottom of ponds or in holes in the ground. Tree toads, if kept in a cage in the winter and provided with soil, will endeavour to cover themselves with it, showing how strong the instinct or habit is. Some fishes are so insensible to heat or cold that when in this condition they can be frozen and carried for a number of days and then be brought back to an active condition. The pond snail passes into a winter sleep as soon as the temperature of the water is below 57° Fahr., that is, they will not digest food or grow until the temperature of the water is at least up to 59° Fahr. Those who have watched the Harlem River from McComb's Dam Bridge cannot have failed to notice the curious appearance of the muddy shores of the river and creeks at low tide. If the sun shines brightly, the dismal beach seems to quiver and scintillate in a most beautiful manner, reflecting the light like so many diamonds. If we draw nearer, this shore is seen to be entirely covered in places with little snails, that, left by the tide, are forging through the mud to regain the water, and the sunlight striking on them is reflected by the glass-like secretion with which they are covered, producing the curious effect noticed. This could be seen in the warm months, but now, not a snail of the countless millions can be seen. They have gone down in search of "hard-pan," there to hibernate until next April. The land snail (*Helix pomatia*) sleeps four months during the year, and does not throw off the calcareous lid that protects it during this time until the day temperature has reached 53° Fahr. Prairie dogs feel the effect of temperature as low as this.

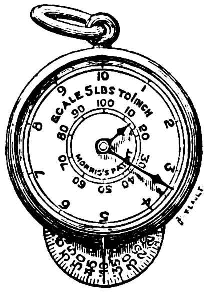
In Cuba reptiles hibernate between 44° and 73° Fahr., according to the species. In warmer countries, snakes, lizards, frogs, etc., fall into a state called chill coma, that precisely resembles winter sleep, but their temperature is far above that at which hibernating animals of the north are still active. The state of hibernation is not the direct result of an extreme of heat or cold, but rather is caused by a departure from the optimum. In the snail its normal temperature is about the same In as the water, and being a poor heat producer, it is not surprising that when the water grows colder the animal is forced to succumb; but it is a remarkable fact that warm-blooded animals like many of the above mentioned, whose bodies are maintained by internal processes at a high temperature of 79° to 100° Fahr., are incapable of resisting the lowering influence of cold. The fall in temperature in some is wonderful; as an example, the high body temperature of warm-blooded animals may be said to oscillate between 97° and 110° Fahr. (this includes man). Experiments made with the zizel show that during hibernation this animal's temperature is only 36° Fahr., the lowest known; and a thermometer introduced into the animal indicated the same, showing that warm-blooded animals in hibernating become truly cold-blooded animals. If a rabbit's temperature reaches 59° Fahr., it will die. The germs of bryozoa or of the fresh-water sponges resist any amount of cold, but the full grown forms die at the first cold turn. Insects are destroyed, but their eggs live, though of the greatest possible delicacy. Salmon eggs have been carried from this State to Australia, and there hatched. In fact, some animals live in the ice, as the glacier flea and several others.

As it is not the direct result of extremes of heat or cold that produces sleep, neither is the awakening from hibernation directly caused by a rise of temperature. In experiments made upon weasels, which are sometimes caught asleep, one came to life in about three hours, during which the temperature of the room remained the same as it had been during the entire hibernation, viz., 50° Fahr. In another weasel, during the awakening, the body temperature rose very rapidly—and more so in the second part of the period than in the first, In the first hour and fifty-five minutes of the awakening the body temperature rose 11·8° Fahr., and in the following fifty minutes it rose 30° Fahr. This remarkable increase took place without any vigorous movements on the part of the weasel. Even its breathing showed no increase in proportion to the rise. These cases show that though, at certain seasons, animals relax as it were and lie dormant, and recover, seemingly at the will of the weather, yet, in point of fact, the rise and fall of temperature has no direct effect upon them. The cause is an internal one, awaiting discovery.

INDICATOR DIAGRAM MEASURER.

Mr. E. RUSSELL MORRIS has invented a handy little instrument (on the principle of the Wealemefna, which, in the absence of a special instrument, is freely used by engineers for the purpose), designed to provide a means of measuring steam engine indicator diagrams with rapidity and accuracy.

The instrument is the exact size of the illustration. By passing it over the (ten) ordinates of a diagram, the *mean pressure* in pounds on the square inch is indicated, the 1-100ths and 1-10ths of a lb. on the roller, and the pounds and tens of pounds by the hands on the dial. Thus the mean pressure indicated in the above illustration is 13·40lb.



The standard of the instrument is 5lb. to the inch. This standard is convenient as, in the first place, being a factor of the Admiralty scales of 10, 15, 20, 25, and 30lb. to the inch, it is merely necessary, when measuring diagrams on these scales, to multiply the result by 2, 3, 4, 5, or 6; and in the second place, each of the divisions representing 1-100lb. (mean pressure) on the roller is a fiftieth of an inch, which is as fine as is consistent with distinct and easy reading. When dealing with scales of which 5lb. is not a factor, the simplest way will generally be to multiply by double the scale and advance the decimal point one place.

The rollers are machine-divided, and the workmanship and finish of the instruments very good.

TELESCOPES AND TELESCOPY.

By Dr. Royston Pigott, F.R.S.

THE following is the substance of a lecture delivered last week, to the Young Men's Christian Association at Eastbourne, by Dr. Royston Pigott.—Long before the telescope was invented the Wandering Stars had been noticed, and at length received the name of planets. But whether the earth was the centre of motion round which all revolved, or whether the sun was a centre, remained for thousands of years an unfathomable mystery. But Daniel arose and confounded the astrologers of the Medes, about the time that Pythagoras first promulgated the true astronomy. This hoary philosopher also taught a plurality of worlds. The earliest recorded eclipse happened in 720 B.C., observed at Babylon. During the Mosaic era clocks, probably water-clocks, were used in astronomy, and Moses was learned in in all the wisdom of the Egyptians. The lunar phenomena were made to regulate the Jewish festivals and years. But I must rapidly pass on to more modern times. Great names begin to illuminate the scene—Copernicus, Tycho Brahe, Galileo, Kepler—Kepler, that man whose grand soul pierced through some of the most abstruse and tremendous facts of the astronomy of to-day. Science now began to dawn. Galileo produced the first telescope and incurred the persecuting spirit of Rome in its most revolting form. Carried away by a most consummate genius he dedicated his life to scientific research, and was utterly victimised by Inquisitorial punishments. He was made to declare on his knees—"I abjure, curse, and detest the error and heresy of the motion of the earth and promise never more to say or assert that the sun is the centre of the world and immovable." For three years he was condemned to recite the seven penitential Psalms.

We can imagine the intense delight of this astronomer, who first applied a telescope to observe the heavenly bodies. Jupiter yielded four moons to his astonished gaze. Saturn appeared in his imperfect glass triple. The moon unveiled her gorgeous mountain scenery. The milky way resolved itself into glittering hosts. The Pleiades, or Seven Stars, became forty. The whole heavens seemed suddenly bespangled with multitudes of stars, hidden for ages from the gaze of mankind. The sun showed his spots, and declared also its rotation—a grand new fact of astronomy. He detected the revolution of Jupiter's four satellites and their eclipses. He announced their grand utility for determining the place of a ship at sea, and formed a table of their movements. His invention of the telescope led him to construct a microscope—he devoted twelve years to its improvement. Schottus, in his "Magic of Nature," mentions a strange fact. A Bavarian philosopher died on a journey. In his box was found a small microscope containing a flea magnified. On looking into the glass they were struck with terror at the sight of a gigantic animal. The philosopher was pronounced a sorcerer unworthy of Christian burial.

But Galileo's tube prospered; good men and true began to think. The visible course of Jupiter's moons analogued our own. The motion of the earth was declared by bigotry to be blasphemous. By one of the greatest mathematicians of the age the altars of Aristotle were endangered. The ruin of Galileo was attempted by false representations to the Grand Duke. Seventy years old was Galileo when the Inquisition pounced on the new hero of scientific research. "What a spectacle," says Bailly; "an old man, whose hairs were blanched with study, watchings, and benefits to mankind, on his knees before the Sacred Scriptures, abjuring the truth in the eyes of Italy, which he had enlightened, in opposition to the testimony of his conscience, and in spite of the manifestations given by Nature through all her works." The States of Holland, aware of the immense value to navigation of Galileo's researches, sent their two astronomers to present him with a gold chain, and to encourage him to persevere in his labours.

Science is also everlastingly indebted to this great and good philosopher for the discovery of the vibrations of the pendulum, on which all modern astronomy wholly depends, as also for the discovery of the law of falling bodies. The hallowed interest in the sorrows of Galileo lies for ever embalmed in the memories of grateful manhood. Bayer named the stars by Greek letters for each group. Hevelius, a rich citizen of Dantzic, devoted his life and fortune for forty years to star studies. He made exquisite drawings of the phases of the moon. Towards his latter end telescope finders or sights were used. In old age he lost all his MSS. by conflagration, but re-commenced, using, however, only plain sight on his instruments. His rival, Halley, used telescopes, and Hevelius the old method, with equal dexterity. Telescopes, just after the Great Fire of London, were now first regularly applied to astronomical instruments. From that day forward the modern astonomy made rapid and gigantic strides. Cassini arose, and in France, at least, re-created the science; the Paris Observatory was placed under him in 1670

Newton now made a reflecting telescope, still preserved by the Royal Society. The largest and best are still called Newtonians. He despaired of destroying the colours produced by glassy refraction. His discoveries have immortally rendered his very name a household word. The telescope, by its revelations of exact movement, enabled him to announce a universal law of gravitation dominating in the heavens; but it was reserved for another century to develop the greatest astronomer that ever lived, Sir William Herschel, who demonstrated that the laws of gravitation also were in full force among distant suns and revolving systems of suns.

Mr. Hall, a gentleman of fortune, discovered in in 1723 a property in crown and flint-glass which destroyed the colours of refraction. Dollond re-invented in 1758, and was afterwards made a Fellow of the Royal Society, for his achromatic telescope. At the present day even his glasses are much esteemed. Mertz, Steinheil, Cook, Dallmeyer and Grubb, of Dublin, now construct them in great perfection; but, perhaps, of all these, Wray surpasses every other maker in the colourless purity of the final image. The moon looks like frosted silver, and Saturn like white marble on black velvet. Then we must not forget the giant tubes made by Alvan Clark, nor the delightful reflectors now constructed by Calver. A mirror by this maker, 37in. in diameter, enabled Mr. Common to photograph Jupiter and his moons, and this instrument, I hear, displays minute stars invisible in the American giant, notwithstanding the splendid skies of the Western continent. Nor must Lord Rosse's magnificent reflectors be omitted, nearly 60ft. long, and above 6ft. in diameter.

But it ought to be remarked that the principle of telescopes was first invented in Old England by Roger Bacon about 1250, and that Leonard Digges, who died about 1573, is said to have arranged glasses by which he could examine very distant objects.

The common principle of these instruments is that of bending the rays of light more or less which emanate from a distant object by means of a reflector or lens. The less the bending of these rays the more distinct is the so-called focus where the distinct image is formed and the larger it appears. The longer the tube, therefore, the more perfectly sharp appears the image. Accordingly, telescopes 150ft. long were constructed. One of 123ft., constructed by Huyghens, was used by the Astronomer Royal Pound to measure the diameters of Saturn and Jupiter. The object-glass was mounted on a tall pole, furnished with a ball and socket joint, a long rod carried a magnifying glass, and the thing was directed by means of a long string.

I must now say a few words on the powers of the telescope. It penetrates space. A 6ft. mirror penetrates about 200 times deeper into space than the human eye. One 19in. in diameter penetrates forty times further. Long after the steeple of a distant church became invisible, such a glass enabled Sir Wm. Herschel to read the time by the church clock. This property is of the greatest possible value in astronomy. Starry universes are fathomed; the glittering glories of these realms of resplendent beauty start forth and astonish our bewildered vision at the awful and the unfathomable depth of the abysses of creation.

Galileo had proposed a new question—the velocity of light. Baffled in finding the eclipse of a satellite of Jupiter happening later than it ought, Cassini and Roemer concluded that it depended on the distance of Jupiter being much greater at one time than another from the earth. Thus the telescope led to the actual discovery of the velocity of light—one of the most important in the whole range of science. Cassini relinquished the problem as hopeless, but Roemer persevered until at length he demonstrated its velocity to be such that it passes across the diameter of the earth's orbit—*i.e.*, through 180 millions of miles in the short space of eleven minutes. This grand fact again suggested light-emission, or emanation, to Newton, but Huyghens suggested undulation like the waves of sound. Hence arose a grand theory of waving oceans of luminiferous ether pervading all space. And, latterly, this sublime idea seems destined to be swallowed up in another, teeming more richly still with wonders and energy, viz., a combined action of electricity and magnetism. The electro-magnetic theory of the universe now being developed, without the telescope, Jupiter's satellites could not have revealed the progression of the days of light and its velocity, and a luminous ether would probably have still remained in Roman darkness. Another still more wonderful outburst of light for the intellect of man to revel in—by the aid of the telescope—is to descry the chemical elements of distant suns, stars, nebula and systems, as well as to detect the millionth of a grain in terrestrial bodies close at hand—I mean the prismatic telescope called the spectroscope. A fine slit in brass pours through it a beam of light. This little slit is spread out 30,000 times by a battery of prisms, and lo! an infinite number of lines and colours mark the chemical components of the light, as seen by the telescope. To read the stars, to read, perhaps, a poison in the glass, to survey equally well the glowing flame of furnaces, and see the carbon dying out—the exact instants for saving millions of pounds worth of Bessemer steel—or to detect the minutest trace of a glowing gas in a burning world—a world on fire—to declare what is glowing to be a gaseous or solid—I cannot recount the wonders of this new application of our noble instrument, surely the gift of God to open the eyes of mortals to the inscrutable wonders of Nature and the infinitudes of creative powers.

Turn we now to some of the overwhelming wonders of the heavens. The telescope has enabled astronomers not only to weigh the earth, the sun and moon, but even the planets and satellites, and the starry attendants of distant suns. The exact observation by telescopes, furnished with the most *recherché* contrivances for precision of measurement, have accumulated data for all time. Unknown planets have been predicted to exist at a certain point in their revolution—from the minute perturbations they produce in neighbouring planets. The gorgeous varieties of system on system; prodigious star clusters, thick with mighty orbs—thicker than the sand on the sea-shore; their silent march along their appointed path; their distance from us, at the clear conception of which the stoutest brain reels and staggers in despair; the rush of comets and the rain of meteors—perhaps such a rain destroyed Sodom and Gomorrah,—all these and a thousand other wonders open up their tremendous meaning to the patient watcher at the telescopic tube.

But human nature, at least, could never have reached the heights of heaven without a rule of measurement. The earth's size was gained by the telescope. Then the moon's, next the distance of the sun and an eight minutes' journey for his rays. What shall we name, then, for a span measure of the stars? The speed of light is the only measure by which we can conceive an adequate idea of telescopic distance. Eight minutes' to the sun! Let us mount a fairy car borne on the wings of light. In two seconds we pass the moon, or, starting from our sun, we reach Jupiter in 40 minutes, Saturn in 80, Uranus in 2½ hours, and Neptune, on the verge of our huge system at last, in four hours and forty minutes. But let us onward in imagination—the nearest star is reached in three years and a half. A speed of 190,000 miles per second gives us 16 thousand millions of miles daily journey on a sunbeam to this Alpha Centauri, the nearest fixed star. The wings of light carry us forward to Sirius in twenty years; to the pole star in an old man's lifetime. But passing beyond the little glittering cluster in which we spend our pigmy lives, the telescope reaches other climes of such stupendous depth in space as baffles all human intellect to grasp the growing greatness. Behold the Nebulæ and their clustering glories, the gigantic groups of blazing suns compressed, as it were, into one huge heap of star dust, each star a thousand millions of miles, at least, apart from the next.

But the prismatic telescope reveals greater wonders than the composition of distant stars and luminous ether; it tells us the rate at which we are receding or advancing in space towards distant suns in miles per second. Further, it startles us with the awful fact that our sun and all his planets are rushing towards the constellation Hercules, and probably wheeling in one mighty orbit around the Pleiades or Seven Stars. Perhaps there is some grand hidden meaning in that sublime passage, "Canst thou bind the sweet influences of Pleiades or loosen the bands of Orion? Canst thou bring forth Mazzaroth in his season, or canst thou guide Arcturus with his sons?" (Job 38, 31.) Knowest thou the ordinances of heaven? Canst thou set the dominion thereof in the earth? Canst thou send lightnings that they may go and say unto thee, here we are? . . . Where wast thou when I laid the foundations of the earth, or who laid the foundations thereof, when the morning stars sang together and all the sons of God shouted for joy?"

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—V.*

Second Lesson in Development.

THE photographer has now, we shall suppose, returned to his dark room. He may lay his dark slide, still wrapped in the cloth, on a shelf, and turning up the white light, make the following preparations. He lays his three flat dishes in a row along the front edge of the table, the one to the left opposite the red light, the others to the right of this one. We shall call the dishes Nos. 1, 2, and 3, beginning at the left. Into No. 2 he pours two or three ounces of the alum solution; into No. 3 about the same quantity of the "fixing" or "hyposulphite" solution. Now he takes the four-ounce measure, and pours into it exactly two ounces of the potassium oxalate solution. To this he adds half-an-ounce of the sulphate of iron solution. The whole will immediately assume a beautifuly ruby red colour; to it he adds about 20 minims of the one per cent. solution of bromide of ammonium. He will now have about 2½ ounces of developer. This is an extravagant amount to use for a quarter-plate, and, if the photographer continues to use ferrous oxalate, he must reduce it to one-half; but at first it is best to use a good dose. Everything is now ready. The white light must be entirely extinguished, and the red light lowered as much as possible, till there is just enough to see by. The plate which has been exposed must be carefully removed from the dark-slide, and laid—film side upwards—in dish No. 1, which is still empty. Now the dish with the plate in it is taken in the right hand, and the measure with the developer in the left. The developer is poured rapidly, but gently, over the plate, the dish being waved or rocked to make the liquid cover any corner which it may incline to avoid, and the whole is placed again in front of the red light. And now (if everything has been rightly done) will commence one of the most wonderful of the phenomena of science or nature which man has been given the power to control—a phenomenon which is always new and always beautiful—the "development of the latent image." Let the beginner watch it closely. The plate had no indication of having been acted upon at all before the developer was poured over it. After, perhaps, ten or twenty seconds there is a slight darkening of some part. When this becomes distinctly visible the light may be somewhat raised, for the plate has become less easily affected by it. It will now probably be seen that the brighter parts of the landscape have become quite visible. In *negative*, be it remembered, the sky will be represented by blackness. Now is the time when we can tell whether or not the exposure has been correct. If it has been, the development will progress with beautiful regularity. The bright parts (or high-lights) appear first; then slowly, but steadily, more and more of the half-tones, or less brightly lighted parts, come out; and at last every object and shade except the deepest shadows have their counterpart in the negative. In other words, the plate should be darkened to a greater or less extent in all parts except those few which represent the part of the landscape which appears to the eye quite black, and this should come about in between one and two minutes. If the plates have been under-exposed it will be longer before the high lights appear, and very soon after they do the action will stop, no more detail coming out, but large patches of the plate remaining white as before. If, on the other hand, it has been over-exposure, the high lights will appear a little sooner, and almost immediately afterwards the whole of the plate will be covered with detail, no part remaining white.

---

* Condensed from the *Photographic News*.

The final result of incorrect exposure is, with under-exposure, a hard picture with contrasts over-marked, and with deep heavy shadows in which none of the detail which is visible to the eye is represented; with over-exposure, a flat, uninteresting looking production, showing all the detail which there is in the original, but lacking the bold contrast of light and shade.

We shall suppose the happy medium to have been hit, if not at the first attempt, after a few more plates have been exposed. The development is not of necessity finished when, looking on the surface of the plate, all action seems to have ceased. We have still to wait till the "density" is sufficient.

It must be understood, that as long as the plate lies in the developer, the density continues to increase, and we may say at once that the most difficult thing of all to judge of in gelatine dry plate work is when the required density is gained. So difficult is this, that even the most experienced photographers may occasionally fail. The reason of this is that the after-processes very much modify the apparent density of the negative, and not only that, but in every different make of plate the apparent density is modified to a different degree. We must make it appear far denser than it is eventually to be. It is only by experience that knowledge approaching to exactness can be gained on this point. We will merely indicate the manner in which it is usual to judge of the density. The red light must be turned pretty high. The plate must be lifted from the developer and held, with the film side towards the observer, for a second only, close to the light, and between the light and the photographer. He must rapidly judge whether or not the density is correct. We may say roughly that, as a rule, the densest parts should appear almost, if not quite, opaque. If they do not, the plate must be returned to the developer.

We shall suppose the correct density to have been gained. The time taken with the developer we have given will probably be from two to five minutes. The developer is now poured back into the measure. If used within an hour or so, one or two more plates may be developed with it. The plate is now thoroughly rinsed under the tap, either held in the hand, or left in the flat dish. After this, as much red light may be admitted as is required. Then the plate is laid for five minutes in the alum solution, to harden the gelatine film. It is again thoroughly rinsed, and placed in the fixing solution. It will have been observed that up to this time the plate, looked at from the back, still appeared white. This is because the sensitive salt of silver which was not acted upon by light still remained in the film. On placing the plate in the hyposulphite, this whiteness will gradually vanish. When there is no farther appearance of it from the back, white light may be freely admitted. The plate must still be left a few minutes in the fixing solution, after which it must be most thoroughly washed. It should remain at least half-an-hour either under running water or in frequent changes of clean water. After that, it is reared up on edge to dry, when the negative is complete. Heat must on no account be used in drying.

Our legal correspondent, Mr. F. Wetherfield, has commenced the publication of a monthly magazine called *The Law* containing monthly notes on legal matters and a digest of commercial cases for men of business. The price is a shilling, and the April number contains articles on Debt Recovery, The Employers' Liability Act, The Mayor's Court, London, What is a Bill of Exchange? Bills of Sale Amendment, County Court Jurisdiction, The Debtors' Act, 1869, Liquidations and Compositions, and an appendix of cases. The magazine is useful, handy, and cheap, considering the character of the information.

At a recent meeting of the Académie des Sciences a new pump for compression of gases was described by M. Cailletet. A special feature is the presence of mercury above a plunger piston, with which the mercury moves. An hour's work will give 400 or 500gr. of liquid carbonic acid or protoxide of nitrogen. The author stores compressed gases in bundles of metallic tubes communicating with each other, and each holding about four litres. Pressures of several hundred atmospheres are attained.

SCIENTIFIC NEWS.

The Dun Echt Circular, No. 49, gives elements and ephemeris of the new comet (Wells) calculated by Mr. Hind. He makes T = June 15·0345 G.M.T.; π = 49° 8′ 24″, ☊ = 205° 19′ 46″, i = 73° 45′ 1″ app. equinox 1882, March 21; log. q = 9·003769. The position on April 15 he gives as R.A. 18h. 53·2m., N.D. 52·1° for Greenwich midnight. The brightness will increase until June 14. The same circular contains elements deduced by Dr. M. W. Meyer, of Geneva, which are T, July 15·040 Berlin M.T., π 307° 43·8′, ☊ 205° 28·2′, i 70° 47·9′, log. q 0·31522. Circular No. 50 contains elements, &c., calculated by Dr. Oppenheim, and another calculation by Mr. Hind. The latter gives T = June 12·07195, π 52° 6′ 33″, ☊ 204° 59′ 33″, i 73° 42′ 44″, log. q 8·870371, and has the following remark:—If I on March 19 = 1, on June 12 I = 2105 "? a daylight object at this time!"

The eclipse expedition to Egypt will consist in all probability of the following gentlemen:—Mr. Lewis Swift, of Rochester, New York; M. Thollon, of Nice; Mr. Ranyard, Mr. Lockyer, Capt. Abney, and Mr. Black. M. Thollon goes at the expense of M. Bischoffsheim, who has chartered a special steam-vessel from Cairo, and has invited Mr. Ranyard to accompany his party, which will include a professional photographer. Mr. Ranyard takes the large camera of 13in. aperture which he used in the American eclipse of 1878, and several others. Mr. Lockyer and Capt. Abney will probably represent the Royal Society.

The Observatory of Popular Astronomy, established in the Trocadéro, Paris, will, it is stated, be transformed into an institute for general popular education in the sciences.

The following are the lecture arrangements after Easter at the Royal Institution:—Mr. Edward B. Tylor, four lectures on "The History of Customs and Beliefs," on Tuesdays, April 18th to May 9th; Prof. Arthur Gamgee, four lectures on "Digestion," on Tuesdays, May 16th to June 6th; Prof. Dewar, eight lectures on "The Chemical and Physical Properties of the Metals," on Thursdays, April 20th to June 8th; Mr. Frederick Pollock, four lectures on "The History of the Science of Politics," on Saturdays, April 22nd to May 13th; and Prof. David Masson, four lectures on "Poetry and its Literary Forms," on Saturdays, May 20th to June 10th. The Friday evening meetings will be resumed on April 21st, when Prof. Dewar will give a discourse on "The Experimental Researches of Henri Ste.-Claire Deville."

At the meeting of the Institution of Naval Architects, held last week, the views of Sir W. Armstrong on smaller vessels and unarmoured cruisers were criticised in the course of a discussion on a paper by Mr. Samuda, in which that gentleman, supported by Admirals Hornby and De Horsey, Captain Noel, and Mr. Barnaby, held that even thin armour was of value, while an unarmoured cruiser was practically of no use at all against an ironclad. Mr. Barnaby also spoke of the size of vessels, and pointed out that a vessel of 8,000 tons and 8,400 horse-power could steam as fast as the *Mercury*, which has the enormous proportion of 2 I.H.P. to each ton of displacement. Amongst other papers read was an interesting one by Mr. Parker "On Compound Engines," which gave rise to an animated discussion.

The Naval and Submarine Engineering Exhibition, to be held at the Agricultural Hall from the 10th to the 20th inst., promises to be one of the most attractive shows ever held in the building.

In the south nave at the Crystal Palace, Messrs. Hammond exhibit a printing-machine driven by a Brush dynamo. Some little interest has been created by a new storage battery, known as the Sellon-Volckmar, which, we understand; is a modification of Mr. Swan's device. Gerard's "slide-lamp," said to be of 400 candle-power, attracts much attention.

Concluding his lectures last week at Owen's College on the "Ancient World and the Appearance of Man," Prof. Boyd Dawkins said that from the standpoint of the present he turned to the past, and saw that man, by continued struggles with nature, had developed his powers until he had come to be what he was; and he looked forward to the future in the belief that in the ages that were coming man would be lifted up above the present level of culture as high as we were removed from the state of savagery of the primæval hunter.

The homœopaths assert that a discovery has been made of a means of checking an attack of typhoid fever. The new drug is called baptisia, and is obtained from an American plant of the order Leguminosæ

We have the Annual Report of the Manchester Microscopical Society, and are pleased to see that the number of members is steadily increasing, and that the funds show a "balance" on the right side.

The properties of the Kola nut, so largely used in Central and Western Africa, where it has a *rôle* similar to that of *Maté* and *Coca* in America, have been lately elucidated by MM. Heckel and Schlegdenhauffen, who, in a paper to the French Academy, give an analysis of the substance. The cotyledons of the seed are the only part the negroes use. The effects are those of a stimulant and tonic; and impure water is rendered agreeable by previous use of the nut. The analysis shows that the Kola nut has more cafeine than the best coffees, and that that substance is wholly free, not combined, as in coffee, with an organic acid. The action of the cafeine is aided by a considerable quantity of theobromine present. Next there is a notable amount of glucose (of which there is none in cocoa). The nut contains thrice as much starch as is found in seeds of Theobroma. There is little fatty matter, and a special tannin, together with a red colouring matter, are present. As a remedy, the Kola nut is appreciated by the Africans in affections of the intestine, liver, &c.; it may be ranked medically with Coca and like matters, over which, however, it has an advantage in possessing so much tannin, which gives it precious astringent properties.

For observation of the transit of Venus this year, the French will have eight stations as follows:—In the north, Florida, Col. Perrier; Cuba, M. d'Abbadie; Mexico, M. Bouquet de la Grye; Martinique, M. Tisserand. In the south, Santiago du Chili, M. Leclerc; Santa Cruz, M. Fleuriais; Rio Negro, M. Perrotin; Port Desiré, or Chubutt (Patagonia), M. Hatt. These missions will start in July. Each will have two equatorials, one 8in. and one 6in. Photographic methods are to be very limited this time; the French will employ them at only two stations, and the Germans not at all. For micrometric measurements, double-image apparatuses, adaptable either to the object-glass or the eyepiece, were recommended by the Conference. Observation with filar micrometers or micrometric network, or with instruments having divided circles, was to be reserved for stations where the stability and regularity of motion of the telescope were sufficiently assured. Careful definitions were given as to the contacts. According to *Les Mondes*, 38 transit expeditions have already been projected, not counting those of Italy, Austria, and the United States, which are not yet fully known.

According to a German paper, the United Königs and Laura Foundry has, within the last two years, been largely supplying pavement made of cast iron and steel, which is valued for its small weight, together with remarkable durability, and finds manifold applications, as for bridges, courts, quays, &c. A pavement of of the kind, on a much-frequented carriageway at the Laura works, has fully answered the requirements, without wearing out or deformation; and the same with some bridges over railways, on which the pavement has been tried some time.

It appears that the German emigration last year to lands beyond sea amounted to 210,547. Of this number 98,510 went by Bremen, 84,425 by Hamburg, 2,434 by Stettin, 26,178 by Antwerp. For 206,189 the destination was the United States, for 286 British North America, for 26 Mexico and Central America, for 58 the West Indies, for 2,102 Brazil, for 762 other parts of America, for 314 Africa, for 35 Asia, and 745 Australia. In the last eleven years the number of emigrants has been, roughly, as follows (in thousands): 76 in 1871, 126 in 1872, 104 in 1873, 45 in 1874, 31 in 1875, 18 in 1876, 22 in 1877, 24 in 1878, 33 in 1879, 106 in 1880, and 210 in 1881.

An elevated electric light is regarded as a great desideratum for the busy crescent of New

Orleans harbour, and a project of the kind by Mr. Golding is illustrated in the *Scientific American*. The tower would be some 500ft. high, and carry a light of 40 thousand candle-power. It is a guy-supported cast-iron cylinder built up of short sections, and reared by additions made at the bottom. A hydraulic lift raises the upper sections till a new section (say 5ft. long) can be placed underneath. The lamp trimmer would mount on a circular platform, forced up as a piston, by compressed air. The cost of a tower, without the lamp, would be about 30,000 dollars. The sharp bends of the river at New Orleans result in a pretty rapid displacement of the river bed; thus the bank at Carrollton Bend has receded about 500ft. in 20 years. It has been attempted (since 1878) to meet this evil by a system of mats of brush ballasted with stone. A board of engineer officers, however, has lately pronounced this a failure, and advised that it be discontinued.

The sickness of persons rapidly transported to an elevated position is probably due to diminution of the quantity of oxygen in the blood, the tension of this gas in the surrounding air being lessened (a condition of the system called by Dr. Jourdanet, *anoxyhæmia*). Those who live on in such places get acclimatised, and the descendants prove quite indifferent to a state of things which gave the first inhabitants much discomfort. What is the nature of this acclimatation? M. Bert has lately tested the view that the blood comes to contain more of the substance called hæmoglobin; it is supposed there is less oxygen for a given quantity of this, but the larger amount of hæmoglobin makes up. He had an opportunity of examining the blood of various animals (vicuna, lama, alpaca, stag, sheep, &c.), living above Paz, a place in Bolivia more than 12,000 feet above the sea; and he finds that, when agitated with air, it is capable of absorbing from 16 to 21 cubic centimetres per 100cc. of air, whereas the maximum of oxygen absorbable by the blood of herbivorous mammalia, in low regions, under the same conditions, is only about 10 to 12 per cent. Thus the hypothesis is verified. Animals in high positions have blood with a higher capacity of absorption for oxygen than that of animals at the sea-level. It is allowed that there are some other elements in the complex problem of acclimatation, but they are probably quite subordinate.

The activity of some humane sportsmen may now perhaps take a new direction, as M. Marey has lately contrived an instrument which, pointed at a bird in flight, like a fowling-piece, and let off, gives easily twelve successive photographic images of the bird. The exposure for each image is 1-700th of a second; but on a bright day it may be reduced to 1-1300th. If the series of images be arranged in a phenakistiscope, the aspect of a flying bird may be reproduced in such a way that the motion may be easily analysed. The principle of the contrivance is the same as that of the *photographic revolver* which M. Janssen made for observation of the transit of Venus.

In the purchase of seeds, so common at this season, one is apt to be deceived. A correspondent of the *Journal d'Agriculture Pratique* recommends a test which he has used for many years with complete success. It is that of *fire*. Take at random a number of seeds from the bag, say eight. Put some live coals on a shovel, and deposit each of the seeds successively on it. Blow the coal, and watch how the seed behaves. If the combustion is slow, merely giving off some smoke, you may conclude that the seed had a damaged germ; if, on the other hand, the seed leaps and turns about on the coal, producing a dry sound (tac), proportional to the size, it may be inferred to have good germinative qualities. In this way the proportion of good and bad seeds may be ascertained. As for the larger seeds, such as acorns and chestnuts, it is sufficient to throw them into a fire, and keep them in view. If the quality is good, this will be indicated ere long by detonation of the seed.

The Boston Manufacturers' Mutual Fire Insurance Company has sent its members a second circular on electric lighting, in which confidence is expressed in the safety of the arc-light "rightly put up and adjusted within the limits of a mill-yard, under control of the manager;" but the policy-holders are advised "not to allow any public telegraph, telephone, or electric-light wires to be attached to their buildings, or to be so placed in or across their mill-yards as to expose their property to the possible danger of diversion of a current of a public electric arc-light wire outside their own control, except such wires as are needed for their own use, in connection with the general service." The circular advises that telegraph and telephone instruments should be placed on a base of glass, marble, or other insulating and incombustible material, so disposed as to catch the drops of metal melted by an accidental overcharge; and suggests that, as its agents have often observed marks of scorching or burning of wood-work round the switches by which electric currents are turned on and off, such switch-boards should be made of terra-cotta, porcelain, or glass.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

WELLS'S COMET—THE PLANET MARS—VARIABILITY OF γ VIRGINIS—TELESCOPES BY THE OLD MASTERS—FORTIFIED ENGLISH TOWNS—REMOVING SPOTS FROM THE LENSES OF A TELESCOPE—2 URSÆ MINORIS—GETTING RID OF ANTS.

[19884.]—It may not be uninteresting to learn the Wells's Comet, to which you devote the first paragraph of your "Scientific News," on p. 78, will be about 7° north of Vega on the night of the day (April 7th) when this appears.

With reference to Mr. Webb's exceedingly interesting letter (19858, p. 79), I would say that the idea of a very close analogy between our own Globe and that of Mars is one that I fancy but few working astronomers have entertained for a long time. That land, water, and polar ice and snow figure among Areographical detail, I feel pretty well assured, from a long course of personal observation of the planet. When, however, we come to study their distribution, we do find a very marked distinction between the condition of things on the Martial surface and that obtaining here; for whereas little more than a quarter of the area of our world is composed of land, it is water which is in defect in Mars. Speaking roughly, we may call the Earth one of Islands, while Mars, on the other hand, is a home of inland seas. The so-called "canals" of Schiaparelli certainly seem to have no terrestrial analogue so far as their real character can be deciphered. I gather, from what Mr. Webb says, that these are as permanent as the other markings on the planet.

Apropos of variable Stars (letter 19860), will Mr. Baird Gemmill look at γ Virginis? The components are rated as being practically equal; but we may assume that the position angle has been measured in the usual way—*i.e.*, that the Star which has the advantage, however small in magnitude, has been selected as the initial point. This, then, would be the Northern one according to the most recently published position angles. Last night, however (March 30th), the Southern Star of the pair seemed to my eye certainly to be *just* the larger of the two.

I do not know whether "L. L. L." (letter 19863, p. 80) is aware that the famous 3¾ "Beauclerc" achromatic was in the possession of the Rev. A. F. Padley, of Lincoln, in 1861, in which year that gentleman advertised it for sale. Tulley's chef-d'œuvre, his 6·8in. achromatic (*Memoirs* of the R.A.S., Vol. II., p. 507) is now in the possession of Mr. C. Leeson Prince, F.R.A.S., of the Observatory, Crowborough Beacon, near Tunbridge Wells.

To answer query 46197 (p. 90) in extenso, would involve an amount of research and investigation which, writing on Friday afternoon to catch the post, it is out of my power to bestow upon it. Speaking, though, off-hand, London was a fortified City, while among fortified towns were St. Alban's, Chester, Hull, Lewes, Shrewsbury, and Great Yarmouth.

Mr. Corbett (query 46526, p. 91) can himself do nothing to remove the spots of which he complains on his telescope glass. From his statement that this is "2in. dia.," I gather that it must be the object-glass of the telescope, and not one of the lenses of the eyepiece. But if this be so, I cannot understand how or why "the spots are a great inconvenience, when looking at anything," inasmuch as their sole effect under such circumstances would be to cause the loss of an inconsiderable amount of light. Any spots which show *as spots* in the field of view must be in the eyepiece. New soft wash-leather will probably remove the particles of dirt producing this undesirable effect; but the objective must be repolished by an optician.

In reply to query 46535 (p. 91) the 5th magnitude star approximately in R. A. 0h. 52m. 49s., and Dec. 85° 37′ 25″ is quite correctly designated 2 Ursæ Minoris in Proctor's "Atlas," and so appears in the Greenwich Catalogue. β Cephei is nearly 20° from this, and 4 Cephei further still. Probably the compiler of Gall's "Atlas" has been misled by the sprawling of the constellation figures in the older ones. In Bode's "Atlas," for example, Cepheus is actually kicking the Little Bear in a fashion of which I need say no more than it is the most insulting that can possibly be conceived!

Has "Negs" (query 46541, p. 91) tried castor-oil?

A Fellow of the Royal Astronomical Society.

SELENOGRAPHICAL—PLINIUS.

[19885.]—On comparing the three drawings you have lately published of the walled-plain Plinius, one cannot but feel the importance of studying this formation more closely. It is impossible, it seems to me, to conciliate Schmidt's drawing with those of Elger, and also with mine, were I to send the one I took on March 25, 1882. Elger's two drawings agree fairly well. The western crater is entire, or nearly so, and the eastern one is open towards the south, though somewhat broken on the north. My observations agree with Elger's, with these small differences: 1st, the N. borders of both craters are formed by separated masses of rocks disconnected on each side from the rest of the craters. 2nd. The plateau N. of these craters is wider, being two-thirds of the width of the two craters. 3rd. The E. border of the W. crater does not run straight S., giving to this crater the form of an inverted ɑ; but turns to the right and partly encompasses the eastern crater, leaving an opening of only about one-third of its circumference. These differences can very easily be accounted for. But what of Schmidt's drawing? No doubt it was exact when made; but could Plinius be thus drawn at present? Both craters are quite open on the N., both are thickly bordered on the S., and neither is connected with the plateau on the N., which plateau has quite lost its present shape. It is to be hoped that observers will have an eye on this object. I may add that the "small, but very distinct craterlet," spoken of by Mr. Elger in his letter 19814, was seen by me for the first time on May 25, 1871. It was also well seen on January 25, 1882. It occupied the place of figure 4 in Mr. Elger's drawing of January 25, 1882.

C. Gaudibert.

[19886.]—On Jan. 26, 1882, the cleft ϙ was seen running from cleft Ariadæus, passing *s.p.*, crossing craters *a*, *b*, and *s*, and reaching, in a straight line, the E. branch of Hyginus cleft. From the valley where this branch of cleft, Hyginus, is generally seen to end, it was seen climbing the E. side of the mountain, crossing the plain, and was lost among the rocks beyond. The cleft δ Triesnecker reaches the prolongation of Hyginus cleft, where it crosses the plain.

Feb. 22, 1882.—Observed Messala. Found a ring on centre, three small craters S.E. of centre, three hillocks W. of centre, and a ridge running from centre southward. Various other hillocks, two craters on the S.W., and a semi-ring on the S.E., whose floor was whiter than the floor of Messala.

February 23, 1882.—Observed Atlas. The cleft which crosses slantingly the S.W. portion of the floor was seen prolonged, in a nearly straight line, about as much outside the crater as it is long inside. The northern cleft was seen running from a crater on the N.W. of the floor to the eastern rampart, and having the form of an S. This is really a cleft, and is quite distinct from a ridge running along a portion of its N.E. side. A good many other details were seen on the floor.

C. Gaudibert.

POSITION OF FLAT.

[19887.]—I should be the first to acknowledge that the more perfect "all the adjustments" are, the better. I was anxious, however, to point out that there was no optical necessity for the flat to be in the exact axis of the tube, but that this was nevertheless its proper place. I beg to thank Rev. N. D. Godfrey (19862, p. 80) for his method of perfecting this, that the reflection of the flat should be central in the mirror, and also central when a stop is used. Mine are perfectly so, and also when the stops are in a frame 6in. beyond the tube, which I find is better than in the tube itself. If this is Mr. Haren's difficulty, he cannot have a better mode of overcoming it.

Fordingbridge. **T. Westlake.**

ASTRONOMICAL—DOUBLE STARS: β DELPHINI, PIAZ. XXIII. 100-101—ζ CANCRI—THE GROUP OF STARS 2 CAMELEOPARDI.

[19888.]—Allow me to tender my thanks to Mr. Burnham for correcting me in my observation of β Delphini. It is plain this double is far beyond the capabilities of any 8½in. mirror or refractor at the present time. I have a few observations of Piazzi xxiii. 100-101. I give them as inserted at the time of observation, hoping they may be of some interest to some of your readers. "Oct. 17, 1881. Air frosty and fluttering, but clear. I carefully examined this group, and obtained the following results:—A*a* was seen as a double; but only, I suppose, because I knew it to be so. B C was seen double with some difficulty, owing I suppose, to the duskiness of the companion. F, D, and E were easy. G was seen only at times; but no mistake about its existence. I used a single lens, power ± 200. Dec. 15, 1881.—101 Cassiopeiæ: The companion to A was well seen before dark; position ± 330°. A Barlow eyepiece helps much. A light fog, air very good. Powers 250, 550, 735, and 900 +. Dec. 16, 1881.—Air frosty and tremulous. 101 Cassiop., companion to A, seen nearly as well as last night, *p.* 330°. +. The *n.p.* star of 7·5, mag. 14, was seen at 5h. 30m. local time—*i.e.*, before dark. January 10, 1882.—The companion of A seen; so also the companion of B.

Pending the answer of Mr. Webb to the question of Mr. Mills (let. 19488, No. 872, p. 326, Engl. Mech.) with regard to ζ Cancri, I give to Mr. Mills the results of my experience. March 11, 1882.—ζ Cancri divided with 5½in. aperture. March 15, 1882.—3½in. side aperture, star not round; 4in., star egg-shaped; 4½in., well elongated, nearly in contact; 5in., divided with a very fine black line between the discs. Air very good.

The group 2 Cameleopardi. "B. M." (Eng. Mech., No. 874, p. 375), gives a field of the group. I observed it with the following results:—Dec. 4, 1881.—Saw 2 double; 6 was doubtful. There were sparkling here and there, between C, D, 6 and 5. Where "B. M." has placed a cross near B I saw a star, 8, and on this occasion I record 8 as easy as 5. Dec. 8, 1881.—Saw 2 double, 6 doubtful. Sparkling here and there between C, D, 6 and 5. 8 was as easy as 5. Dec. 24, 1881.—Observed the group 2 Cameleop. The air was so bad that neither of the two doubles were seen as such. It was difficult to find a focus. I saw C, D, 1, 2, 3, 4, 5, and 8. With me 6 is very doubtful, with any power. B has a companion *n.f.*, and 2 is double, *p.*, ± 60°, 6 or 7. **C. Gaudibert.**

RULES FOR FINDING THE FOCI OF LENSES.

[19889.]—If we have a convex lens, our first wish is to know its focal length, or the distance of that point behind it in which the rays it transmits are compressed into the smallest possible compass. The most natural way of finding this quantity is to take a card, hold the lens in front in sunlight, and slide it to and fro until the smallest disc of light is obtained. This is the focal point, and its distance from the lens is the focal length. The quantity so found is termed the solar or *principal* focal length, and is the standard by which we compare the powers of lenses. The terms "focus" and "focal length" are used indiscriminately, and, when we speak of a lens having, say, 10in. focus, we mean that, if held towards the sun, it would form a solar image at 10in. distance behind it.

This is a practical way of finding the required quantity, but we can also determine the result by calculation, provided we know certain things concerning the lens we are using. These are: first, the *radii* of the spherical surfaces of which our lens is a part; and second, the *refractive* power of the glass of which the lens is made. For every species of glass, there is a refractive index, consisting of a whole number and a decimal fraction; cut away the whole number and the remaining decimal part is the *refractive power*. This is the measure of the action of the glass upon rays of light, and it must be known before any focal calculations can be made. For convenience, this number, whatever it may be, shall be denoted by n; let R be the front radius, r the back ditto, and F the principal focus; then the fundamental focal equation is $F = R \cdot r \,/\, (R + r)\, n$. Or, put in words: Divide the *product* of the radii by their *sum* multiplied by the *refractive power*. This applies to the double convex lens; but the rule for the double concave is exactly the same, only F must be called negative, because its focus will be unreal.

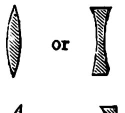
If one surface be flat, the equation becomes $F = R \,/\, n$; or divide the radius by the refractive power. Hence the focus will be real or unreal, according as the radius is convex or concave.

When one surface is convex and the other concave we must take their difference instead of their sum in our divisor; that is, the equation is $F = R \cdot r \,/\, (R \backsim r) n$. If the convex radius exceeds the concave, or R is greater than r, the lens will be a concavo-convex, and will give a negative focus; but if the convex is the lesser, it will be a meniscus, and will give a positive focus. It will perhaps be advisable to exhibit these results in a tabular form with a figure corresponding to each. The upper or + (positive) sign relates to the first form, and shows the focus will be real, while the lower or − (negative) sign relates to the second or concave lens, and denotes that the lens has only an imaginary focus.

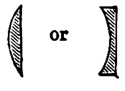
Table of Focal Values.

R, Front radius; r, back radius; F, principal focus; n, refractive power.

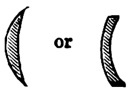
1. Double convex, or double concave .... $F = \pm \dfrac{R \cdot r}{(R + r)\, n}$



2. Plano-convex, or plano-concave .... $F = \pm \dfrac{R}{n}$



3. Meniscus, or concavo-convex .... $F = \pm \dfrac{R \cdot r}{(R \backsim r) n}$



Next, we will assume that it is required to produce a lens of given focus, by curves having a given relation to each other, and of glass whose refractive power has a known value (n). Let the ratio of the front curve to the back one be $R : r :: q : 1$, or $R / r = q$. Then, if F, q and n be given, $R = F (q + 1)\, n$, and $r = R / q$, for the double convex or concave form.

For the meniscus we shall have (since q is in this instance less than 1), R (positive or convex) $= F (1 - q)\, n$, and r (negative or concave) $= R / q$.

For the concavo-convex, q is greater than 1, because the front radius is the greater, and R (as before) $= F (q - 1)\, n$, and r (as before) $= R / q$.

Let us illustrate these rules by one or two examples.

Ex.—A double convex lens is made of glass, whose refractive power is ·52: its radii R and r are 4 and 12 respectively: what is its focus?

$F = (4 \times 12) \div (4 + 12) \cdot 52 = 5{\cdot}77.$

If the second radius r had been concave (thus making it a meniscus), what would have been its focus?

$F = (4 \times 12) \div (12 - 4) \cdot 52 = 11{\cdot}54.$

Ex.—It is required to find the radii in the proportion of 1 to 3 of a meniscus lens of 10in. focus, the material being flint glass, having a refractive power of 0 6? Here $R : r :: 1 : 3$, that is $q = \frac{1}{3}$.

R (positive) $= (1 - \frac{1}{3}) \cdot 6 \times 10 = 4$. r (negative) $= 4 \times 3 = 12$.

Supposing it had been required to form a concavo-convex lens of 10in. negative focus, with radii as 4 to 1 out of the same material, we should have: R (positive) $= (4 - 1) \cdot 6 \times 10 = 18$. r (negative) $= 18 / 4 = 4{\cdot}5$.

Where the two sides of a lens vary in character, I have assumed that the convex is the front surface; but if the lens be reversed, it will not alter its action, and the focal length in the two cases may be taken as equal. It is not accurately so, but in these approximate formulæ it is not necessary to take the thickness into account. In my next paper I will deal with conjugate foci. **O. V.**

TO "TEMPUS."

[19890.]—In reply to "Tempus" (letter 19853), I do not recommend amateurs to *open* brass holes, but make them to the pivot. My reasons are that when the verge is in the turns, it would (I think) be easier for the amateur to make a nice small pivot, finish and polish, without having continually to remove the carriage to offer it, to the bottom hole especially; he can make his hole, as explained in "How to put a Hole to Cock-plate" without losing his Position; the bottom hole he will find more difficult, but with a little practice he will, I think, succeed. If he drills the hole through, puts in a bush with the hole drilled in centre, I don't think he will lose his position at the bottom hole. You see, I want him to finish his verge without removing it from the turns; he can do it which way he thinks is easiest. The holes, too, are generally worn, and I find that new holes are an improvement in escaping. I forgot to mention that he must generally shorten the pallets of the verge; this may be safely done by making a narrow saw-cut in a piece of hard wood, letting the pallet rest on the outside of the cut. When he files it with a fine file, he will find the pallet will bite against the sides of the cut and hold firm; only he must be careful not to file it too much, and see that he does not leave any burr on the face of the pallet.

I am not a self-taught man: but I admit that some of my instructions are original, as I thought it would be easier for a beginner.

I do not recommend interfering with the balance. I think the amateur will get taken in if he tries some of the old balances, they are generally pretty hard.

What part of the cleaning did I neglect? I do not want to take up more room in this paper than is necessary.

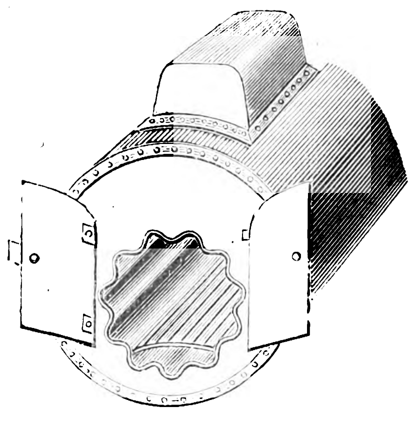
I suppose I began at the wrong end; but I thought I would begin at the escapement, and go right through the watch, to the best of my ability.

I shall be only too pleased for any workman to criticise what I write; and if he can offer any better or easier method, why not do so? It would help to make my articles more complete.

A Fellow Workman.

MODEL STEAM-BOAT BOILER.

[19891.]—"E. L. P." (19846) has given a very good idea for increasing the heating-surface of model boilers. May I also give one which I have tried and found to answer very well indeed? It consists of a corrugated furnace instead of using tubes, and though it might not answer in a large boiler, works well in a model. If sheet brass the thickness of a new farthing be used, the bending will be found an easier matter than fitting tubes. The following drawing will explain better than a long description. **F. G. B.**



PANORAMIC SLIDES FOR THE MAGIC-LANTERN.

[19892.]—Some twenty years ago, when I was an assistant engineer in India, I invented and patented a panoramic camera, but other matters engaged my attention at the time, and besides, strange to say, a patent was taken out in England by a Mr. Johnston, for a camera, made on the same principle as mine; some few years after this I improved on the invention, and when on leave in England, I had a camera made in London, which took two pictures simultaneously: these pictures were stereoscopic, and each took in a view of 180 degrees. This instrument was exhibited at one of the London Photographic Society's meetings, and was examined with some interest. It, however, was too expensive for general use, and a special stereoscope had to be made for it; besides, it was rather unwieldly, being about a yard wide. It was also somewhat complicated, owing to the fact that the collodion-plates had to be flat, whereas the pictures produced by the lenses were circular. I inclose, for the Editor's inspection, a picture taken by this instrument, a view of Falmouth Harbour; this view takes in an angle of 180 degrees, so that, looking at an object represented on the left of the picture and then at an object on the right, the spectator would have to turn "right about face."

In these days of gelatine films, and gelatine paper, a camera could be made of very simple design, as the films or paper would adapt themselves to any curve; besides, the gelatine being so much quicker than collodion, no clockwork (which was a feature of Mr. Johnston's camera) would be required, as one sweep of the lens would produce the picture.

The principle of the panoramic camera will be understood by the following illustration:—I f we hold a single lens between the first finger and thumb (holding by the rim), and using these as pivots, we can turn the lens round its diameter in any direction; now hold it near a wall opposite a window, so that a picture of the window is produced on the wall · it will be found that we can turn the lens through a considerable angle round its vertical diameter without moving the picture that it produces. In the same way it can be shown that there is some vertical line between the two lenses of the ordinary combination used for portraits, round which the combination may be turned through a small angle without the least interfering with the picture it produces.

In my camera, I used small combination lenses by Ross, focus about 3in. (to back lens), front lens about 1¼in. diameter, back about 1½in.

In order, then, to make a panoramic camera suitable for gelatine films, we should have to ascertain the "neutral axis," as we might term it, of our combination lenses.

This is easily ascertained by experiment. Now measure the distance from this neutral axis to the image of a distant object produced by the lens on a sheet of paper or ground glass. This distance will give the radius of the curve of the gelatine film, and the dark slide must be made to this curve. The camera would have to be made of a fan shape; that is to say, the top and bottom would be of this shape, the sides being vertical. The apex or handle of the fan would have to be cut off so as to allow of the lens being placed there. The lens must work between pivots above and below, these pivots being exactly in the neutral axis: and of course some arrangement will have to be made to allow the lens to turn freely without admitting the light. The circular part of the fan-shaped camera must be left open to receive the curved dark frame. Now suppose the lens to be placed in position between the pivots: we attach a tin tube to the back lens of the combination inside the camera, the tube being of such a length that the end farthest from the lens will be within a short distance—say, half an inch—from the sensitive film. Now imagine the tube to be squeezed together sideways, beginning gradually at the end attached to the lens and working towards the other end; we can squeeze it so that the free end will be a mere slit—say, a quarter of an inch wide, and about 3in. high, or about the width of the picture we wish to take.

All the light from the lens will have to pass through this slit, and as the lens is turned in any direction, the slit passes over the sensitive surface.

All that is necessary to take a picture is to place the sensitive film in the dark slide (the film will adapt itself to the curve), place the dark frame in the camera; then, with one motion of the hand, turn the lens through the whole angle that it can turn, and the picture is taken.

The picture I send as an example was taken on a collodion plate. The lenses above described were stopped down to about ½in., and the slit was about ½in. wide, and the whole was taken in about two seconds; with gelatine films, of course, more stopping down of the lenses could be done and a narrower slit used, so as to obtain a microscopic picture.

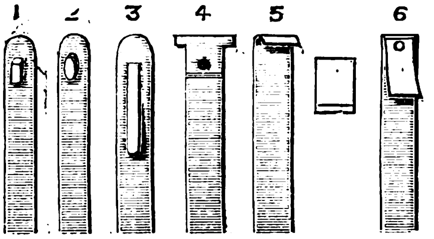
Transparencies printed from negatives so obtained could only be exhibited in the magic-lantern bit by bit; but this is much better than the peep-show views we are accustomed to. If it were not for difficulties about lighting, there is no reason why the principle of the moving lens should not be applied to the lantern, so that we could see the whole panorama at once. The above is a mere verbal sketch, but I could easily make drawings or give further details if the subject is considered of sufficient interest.

Garelochead, N.B. **M.I.C.E.**

WATCH MAINSPRINGING.

[19893.]—The subject of fitting mainsprings to watches is one, I think, which has received but scant attention in the columns of the English Mechanic. Occasionally queries and answers of a desultory kind have been published, but little of a comprehensive character, which dealt with the work of mainspringing in all its phases. The subject is one of paramount importance to all watch-repairers, and, in a remote way, to watch-wearers. I am induced to take this subject up for the reason previously mentioned, and that because information is so frequently sought as to the manner of fitting new springs to watches. Although I take it that the majority of these queries emanate from "outsiders," I still think that much information may be imparted to, and be welcomed by, those who are beginners in the trade, and have only just come within the "pale." In these days of half-and-half apprenticeship, when many young lads are in a measure left to their own resources to "pick up" what little knowledge may be gleaned by observation rather than actual teaching, a few words of practical instruction and advice may serve to help a few of the lame dogs over the stiles of difficulty they meet with at almost every turn in their daily work. When it is considered how large a part the mainspring plays in the economy of a watch, seeing that it is the life, so to speak, thereof, it will not, I think, be occupying space uselessly if a little close study of its action, mode of fitting, relation to the barrel, some causes of breakages, advantage and disadvantage of stopwork, and the benefit of sliding-clicks, be made.

It will be necessary to set before the reader figures of the various forms of hooking and attachment of the ends of the mainsprings to the barrels. I apprehend that the treatment of such questions as these may to many appear needless; so to those I would say, Pass it by. The following examples of spring-hooking will show the various forms now in general use. References will be made to them as I proceed. Until a comparatively recent period only about two forms of hooking were in vogue, and these are depicted in Figs. 1 and 2. Fig. 1, with the hook made of steel, riveted to the end of the spring, and fitting loosely in a correspondingly shaped aperture in the barrel ring or rim as it is sometimes called; the hook being sloped and undercut to the pull of the spring, and the face of the hole sloped in like manner, thereby insuring that the hook be not pulled out when the tension is on the spring. In Fig. 2, the hook, instead of being attached to the spring, is screwed or riveted in the barrel-ring, and its protruding point undercut a little to catch and hold the spring, which, it will be seen, has a hole made in its extremity. Each of these forms—as, in fact, do all the others—have their advocates, and, all things duly considered, not without reason, although it cannot be denied that a given make of hooking may be quite unsuited to a given make of barrel. There seems to be no rule as regards this—various makers selecting whichever form pleases them best. This, then, brings me to the desired point, i.c., which form of hooking is best for this barrel or that. In modern lever watches one more frequently finds the hook fixed in the barrel, and where the hook is made of good brass, of a consistent strength, and properly fitted and shaped, no form of hooking, to my mind, is safer. In practice it is frequently found that with the form of hooking in Fig. 1 the spring breaks close to the riveting. One reason being that the end is not properly softened; and the other, that enough room in the hole is not left to accommodate the swell of the rivet when hammered over. In consequence of which, the metal round the hole is unduly strained, and a fracture there, sooner or later, results. My practical readers will endorse what I say of this form of hooking, that even when the barrel has been adapted to the hook-on-spring style, the hook-on-barrel has been substituted for it, because it has, from one cause or another, failed to hold securely. This is evidence that the hook-on-barrel style is more reliable.



I hold that this form is best, but with this proviso, that the hook is properly fitted. Frequently, from want of careful fitting, the hook "draws," and a new one is needed. I will speak, further on, upon the subject of fitting these hooks, as it is to young hands a source of frequent trouble and vexation. In all the better and middle-class of Geneve watches the form of hooking is as in Fig. 2, where the hole is made in the spring, and the hook fixed in the barrel. In some of the cheaper grades of these watches, as also in some of the lower class Americans, the forms of hooking are as in Figs. 5 and 6, whilst Figs. 3 and 4 represent respectively the better-class American and the English Company's styles. Taking these examples in the order here described, we have in Fig. 5 a very rough and ready form, which, although possessed of strength and reliability, is certainly a very bungling way of attaining that end. In this case either a pin is fixed in the barrel ring, against which the short piece of spring is drawn by the hooked end of the mainspring, or a slot is cut in the barrel-ring which answers the same purpose. The same remarks will apply to Fig. 6, excepting that in this instance: the short piece is riveted to the spring instead of being merely caught up by it. The action of hooking up is the same.

In Fig. 3 we find the same principle carried out in a neater and improved form; but, to the ordinary English workman, more particularly in the provinces, this form of hooking is hardly practicable, inasmuch as very few indeed keep springs of that make in their stocks, and, as far as I know, no punching tool for the purpose of producing the tang from the substance of the spring has yet been brought out by trade tool-makers or vendors. If these springs get broken, comparatively few workmen take the trouble to procure a new spring of the same sort: they invariably take an ordinary lever or strong Geneve spring and rivet a small, narrow piece of spring to its end, or break off the portion of the original spring, as represented in Fig. 3, and rivet that to the new one. This practice is bad, because, either from the rivet-head projecting, or owing to the thickness of the additional piece of spring, valuable room is occupied to little purpose. However, one or two advantages accrue to this form of spring, which greatly outweigh objections on the score of replacing if broken. These are that the probability of "blocking" by undue friction, and the chance of the spring giving way at its hooking-up, are reduced to a minimum. In Fig. 4, we have the English Company's form of hooking or pivoting, as it may more correctly be called.

In conjunction with their patent sliding-click, this form of attachment has little or no fault to be found with it; all that is needed to insure safety being that the pivots be properly set in the barrel-bottom and the cover. Blocking of the spring in the barrel is impossible with these, as, after winding, the returning click allows release to the spring. If the spring gets broken, the small pivoted piece may readily be riveted on a new one. Thus far I have endeavoured to put before my readers the prevailing modes of hooking among watchmakers of the present day. I will not say more as to their merits or demerits, as each in its proper place serves, for good or bad, the purpose for which it was intended.

It is needless for me to enter into a long course of instructions as to the manner of making the various forms of hooking, as anyone having even a very slight knowledge of the use of a file could make and shape as required. In fitting the hook, as in Fig. 1, the rivet should be kept well forward to its face, to prevent the point or edge of the hook rising above the surface of the barrel ring, as the spring is wound up. Should this occur, and not be corrected, the chain may be forced outwards, and catch up in the potence "chain-hollow," thereby stopping the watch.

Apart from the subject of hooking, there are other matters having a bearing upon the subject of mainspringing, which are of great importance to correctness of fit and proper working, and the first of these which I will treat of is the before-mentioned "blocking." By "blocking," I mean that state into which the spring gets when too tightly drawn up.

The friction of the coils one against the other is so great that the tendency of the spring to uncoil itself is overcome, and there is produced either a total loss of power, or the power is exerted with difficulty, until a sufficient "release" has come about to enable the spring to uncoil at an equal rate of speed.

Again, if the number of coils of spring in the barrel is too great, a less number of turns is got than with a shorter spring. If a spring is too short, then the like fault results, so that the mean of these two extremes is the length to be sought for. There are various theoretical and mechanical modes for determining the length a spring ought to be, but most workmen trust to judgment and the eye alone, and when much practice has been had they seldom fail to get a correct length. One very good rule is to divide the space between the arbor and the ring of the barrel in two parts, and let the spring fill one of them. This invariably allows a correct space for the spring to work in. Where stopwork is fitted to the barrel, and is in perfect working order, the mainspring is always at a tension, *i.e.*, it is never fully down, nor ever fully wound up, consequently "blocking" of the spring never happens, excepting it be fouled with dirty, hard oil, which prevents the coils gliding over each other easily. All springs require free oil to them, so any dirty oil should be cleaned away, either by removing the spring from the barrel (which is best done by taking hold of the *second* or *third* coil and easing up gently, not by the *first*, which is generally soft and easily bent), or by working a thinly-pointed peg between the coils as far as possible. In cleaning a watch that has been running a long time, it is always wise to see to the cleanliness of the mainspring. This, being the source of power, should in every respect be free. It it no uncommon thing to find the stopwork wheels either partly or altogether removed from the barrel. Generally speaking, the stopworks are badly fitted, or in the course of time get badly strained, and are a source of evil to the watch unless corrected, replaced with new, or altogether removed; which last, I think, is more frequently done. When the stopwork is perfect in its action, the full force of the winding, at the last pull, is not felt at the barrel-hook because the stopwork takes it; but when it is absent, then the hook takes the whole strain, and it is in such barrels that strong and reliable hooks are most needed, and the weak and insecure ones fail. When the spring is fitted with a tang, stopwork is seldom or never used.

I will now direct the attention of my readers to some known causes of breakage, which may in a great measure be obviated by care in fitting. My experience has been that eight out of a dozen springs, more particularly in watches of a common class, get broken in either the second or third coil. I attribute this in some measure to inattention to the size and make of the arbor hook, and to want of correct tempering of the inner coils of the spring. In the earlier and the better class of Geneve and English watches, it was usual to cut away a portion of the arbor, thus having the hook contained within the circle of the "roller," as it is sometimes called. Consequently, the spring is wound round a true circle, and not anyhow, as is too frequently the case where the hook is sticking a considerable distance out of the roller. In this case, the spring is unevenly coiled, and from the pressure of the outer coils against the inner, and these against the hook, which presents only a point, be it remembered, and that right in the *centre* of the breadth of the spring, it cannot be at all wondered at if the spring does break. In no case should the hook be left longer than is necessary to catch and hold the spring, and the inner coil of the spring should fit close round the roller. The roller-hook should be a little undercut. When a new spring is fitted it should always be observed to have a sufficiently large hole in its inner coil to fit on the roller-hook, without its being pressed up or down in the barrel.

Always examine the new springs for any specks of rust. If marked with it, it is always wise to discard them, as the smallest particle of rust may prove fatal to the durability of the spring. Where springs are kept in quantities, it is a very good plan to cover them with thoroughly dry slaked lime. Springs may be kept for years, without a sign of rust appearing upon them, if treated in this way. Being only a dry powder, the lime may readily be removed by wiping. It is no uncommon thing, either, when a spring breaks, for the hook in the barrel-ring to be forced out, and so necessitate a new one. In doing this little repair, the hole should either be fresh tapped, or a new hole drilled and tapped, if the old one be too large. Never insert the old one and secure with solder, as is frequently done; it is a horrid patch, and never safe. In fitting a new hook, it should be observed to have the thread on it one size larger, according to the number of the hole in the tap-plate, than the tap was with which the hole was threaded. For example, if the hole was threaded with a No. 10 tap, the hook should be threaded in a No. 9—*i.e.*, one size larger. This insures a tight-fitting screw. The point of the hook should in all ways be finished before screwing in, so that only cutting off and filing down outside the barrel is necessary. Occasionally one sees a hook made by inserting a piece of wire in a drill-hole, turned round, and soldered. This, at its best, is a wretched and unworkmanlike way of doing what, even when done in a perfect manner, is only a simple job.

Always take care, in fitting a new hook, that the hole comes in the centre of the ring. If otherwise, the spring, unless it has a large, square, hooking-hole, will be pressed upwards or downwards in the barrel, and so be bound. Always keep a little clearance between the springs and the barrel-lid.

If the lid, when pressed home to its seat, rests also on the spring, it will undoubtedly be bound, and be robbed of much of its power, and so cause it to act in a jerky manner. Always clean out the barrel-holes and the arbor, and re-oil them. In pinning on the stop-finger of a Geneve barrel, care should be taken that in doing so it is not pressing on the barrel-lid. The least portion of clearance suffices. It may have seemed needless to allude to these little matters, but it is well-known that watches frequently stop through neglect of these seemingly trite faults. Remember that small leaks sink great ships, and that one or two apparently insignificant errors may cause the worker more trouble, if neglected, than might a glaring fault which he feels cannot be passed over without correction.

It is always false economy on the part of the repairer to put cheap springs in watches; the difference in the cost of good and bad is but small.

When fitting springs with hooks riveted to them, the workman should always shape the hook and polish its face before it is put in the barrel. If finished off after, as is far too frequently done, the gilding on the barrel will be sure to be injured in the process. The rivet of the hook should be kept well to the front, so as to prevent the face of the hook rising after the spring is wound in the barrel. Never, on any account, if possible, wind in a spring to a verge or lever barrel without the proper winder. If wound in the barrel by the fingers alone, it is sure to get telescoped, and, consequently, will not work free in it. Geneve springs may in some cases be wound in with the winder, and in others by hooking the inner end on the arbor roller, placing the thumb on the barrel-lid over the spring, and turning with a key. See, too, that the arbor has end-shake when the lid is put on. Should a barrel lid fit loosely, burnish the edges over with a tool until tightness is obtained.

When winding in a spring, never let the recoil be great, and the hook snatch into the hole, or the spring on the barrel hook. It may either be injured or torn away by doing so.

I would like, now, to say a few words to watch-wearers ere I conclude my rather lengthy letter. You get very much vexed, do you not, when you hear that ominous buzzing, whizzing, rush of the spring, when it has departed this life? Of course you do, and, mentally, you anathematise the workman who last had your watch in hand; but you think yourselves blameless. Not so fast, good friends! Take a piece of cotton thread, and attach to it a weight, say, a pound or so; lift it gently, and you will raise the weight in safety. Now set it down again, and with a sudden jerk try to raise it again. What is the result? Why, the thread breaks, of course. So it is with the spring of a watch. Either through a badly-fitting key, or a spasmodic rolling-up-a-well-bucket style of winding, the spring is unduly jerked and strained, and soon or late "is not among the things that are." Wind up smoothly and regularly, and ten chances to one a good quality spring will last many years. I have seen springs in good working order after fifty or sixty years' wear and constant usage. Something more than mere quality of metal must have contributed to such a long-drawn-out existence.

I had intended to have written a little about punching, and otherwise making the holes; but my letter has been spun out to such an abnormal length that I fear it will be excluded if I trespass any further. **Alfojoe.**

WATCH REPAIRING.

[19894.]—"A Fellow Workman" begins by saying that his article is intended for amateurs, a class of beings requiring in the general way full and clear instructions. And then he proceeds, at a tremendous rate, to cram the art of watch-cleaning and repairing into less than five columns of the "E.M.," the paragraph on putting in pinions being tite cream. He really must forgive me for saying that the drawings would puzzle a practised jobber, let alone an amateur. Far better would it have been had he taken up the same space with instructions for taking to pieces and cleaning, and left the rest for future articles. I appreciate the spirit in which the article was written, but the article itself must be condemned on account of its *extreme* briefness. I also noticed a short time back that "A Fellow Workman" advised a querist to scrape the end of a hair-spring to make the watch go slower, and he must again forgive me if I tell him that a more barbarous method does not exist, the action of the spring being entirely spoilt by such treatment. His method of putting in new holes means repitching the depths—no easy job for an amateur. I would suggest the use of a bouchon (100 for 1s.). I would also inform "F. W." and "Skip" (p. 65), that it is very bad practice to allow a dirty watch to run down. I used to do it myself once; but after having had the extreme pleasure of twice seeing the 'scape-wheel start out of its place minus a pivot, and the watch go down with a rush, I relinquished the practice. Always let down the mainspring *first thing* in a Geneva, and next to removing balance and dial in an English watch. **F. C. Putley.**

DYNAMO-MACHINES.

[19895.]—I waited with not a little interest for the description of the wonderful machine which "Conrad" foreshadowed some time ago. Now that it has been described, I am somewhat disappointed, and the most powerful objection I have to it is, that it will give no current. We are not concerned at present with the way in which the magnetic field is mapped out; but "Conrad" possibly knows of the existence of what are termed lines of force, and that the current generated in a closed coil moving in front of a magnet is proportional to the addition or subtraction of lines of force cutting the coil. Let W be the work done in moving the coil from a position where N, lines of force, cut it to another position, where N, lines of force, cut it. C = the current in the coil, E = the electromotive force, then $W = C (N - n)$. But the work done by the coil must equal the work done in the coil, and the work done by the coil is ECt $\therefore ECt = C (N - n)$ where t = the time in moving the coil. $Et = (N - n)$ and $E = (N - n) / t$, or the electro-motive force is proportional to the rate of adding lines of force. Now, in "Conrad's" machine, so far as I can see, lines of force are neither added nor diminished during the rotation of the armature to any appreciable extent. The lines of force will cross straight over from one pole to the other, and each coil will cut precisely the same number in every position. "Conrad" appears to think that sloping the poles will give him the desired effect, and it might do so to a very slight extent if there were no iron in the cores; but as he has drawn it I question if he will get a measurable current at all. It is not the fact of the iron cores being magnets that induces a current, but the fact of their magnetic condition being changed, and if there is no change in the condition of the core there is no current. So if the cores of "Conrad's" machine are not magnetised and demagnetised to a certain extent—that is to say, if there is no heating in the iron of the core—there is no current in the coil. To be sure, the ends of the cores on one side next the N. pole are all south, and remain S.; but if lines of force are added and subtracted (although how this can be in "Conrad's" machine is a mystery), these ends must be South, and more—South alternately, otherwise there can be no current; in other words, there must be magnetisation and partial demagnetisation of the cores; therefore, there must be heat in the iron. When "Conrad" hinted at his machine two or three weeks ago, I hope it will not pain him if I say that I never believed he could do what he professed; indeed, he does not properly understand the principles of dynamo-machines in their simplest application; and "Conrad" could do worse than take "Humble Bee's" advice. **E.**

[19896.]—I am sorry that "Conrad" (letter 19882) should have taken my advice to would-be constructors of dynamos in the personal sense he apparently has done. It was bona-fide advice to a class, calculated to help them to attain their desires.

Although the following remarks will be upon the substance of "Conrad's" letter, I trust he will take them in good part, and as meant for the general benefit and instruction. I fear that much useful discussion is lost to the English Mechanic on account of the tendency which many hon. members—I should say, correspondents—display to personalities and imputations of ignorance, &c.

"Conrad" admits that my statements with regard to the Brush machine, and his conception of its action are true. Now, that seems inconsistent, as he says that, during one quarter of a revolution *only*, the coils produce a current, while I say that during that particular time they are out of circuit altogether. Will "Conrad" tell us in which part of the revolution the bobbins are effective? He does not deny the cutting out of the coils.

"Conrad" is mistaken in his premise that currents are *only* induced in wires when the inducing power (intensity of magnetic field, I presume he means) either increases or decreases. That proposition involves another—viz., that a current cannot be produced in a wire moving in a uniform direction in a field of uniform intensity. But the reverse is the case. A current can be induced in a wire moving in one direction in the earth's field, which is sensibly constant for a large space.

The true law of electro-magnetic induction is, that the E.M.F. induced in a conductor is simply proportional to its velocity and the strength of the field in which it moves; in other words, to the number of lines of force cut by the conductor in unit time. Chapter IX. of Fleeming Jenkin's "Electricity and Magnetism," goes into the whole matter simply and thoroughly, and is worth careful study by all interested in these questions. Now, the Brush machine has its coils rotating in a nearly uniform field in one direction for about three-eighths of their rotation, and in a similar field of opposite direction for an equal time. Perhaps "Conrad" does not know that the opposing poles of the Brush machine are similar; if they were unlike, there would be no current.

The iron in the Brush armature takes a considerable part in making the direction of the lines of force perpendicular to the direction of motion of the coils.

The heating of the iron is certainly objectionable; both as a loss of power and as dangerous to the insulation. It is doubtful, however, that reversals of magnetism are the chief cause of this heating. Internal induced currents are more probably the cause.

"Conrad's" machine will undoubtedly produce a current; but the changes in the intensity of the field are so small compared with what takes place in other machines, that he will require a great weight of wire on the armature to give a good E.M.F., or a very high rate of speed. The latter method is limited, however, by the fact that the magnetic changes in iron take time; there is, therefore, a limit to useful increase of speed. Although "Conrad's" armature-iron is not reversed, yet its magnetism is continually altering in intensity—the difference is one of degree, not of kind. In the Siemens direct-current machines, the iron in the armature does not rotate; its magnetic condition is constant, and there should not be any heating in it. Like the Brush armature-iron, it directs the lines of force in a perpendicular to the wires. Probably the modern Siemens machine is the most efficient in use theoretically; practically it is not wound to give the highest efficiency in external work. The Edison is practically a Siemens machine, but with a rotating core—which is a doubtful improvement. Probably the best dynamo will be one without iron in its armature, or only a little, to direct the lines of force, and that little not in motion.

I hope a few others will take up this subject; it should be of great interest now.

Humble Bee.

RAMSDEN'S DIVIDING MACHINES.—PART I.: THE CIRCULAR DIVIDING ENGINE.

[19897.]—Through the kindness of "Ascalon," I am enabled to supply the drawings and description of Ramsden's apparatus. The description may be conveniently divided into three parts: of these, Parts I. and II. relate to the circular dividing engine, and Part III., to that for dividing straight lines. Ramsden was the first to construct a machine which would divide circles or circular arcs with anything like accuracy; and though his invention has, doubtless, been superseded by modern and more delicate mechanism, yet the account will be read with interest; especially his method of ratching or cutting the teeth of the main wheel.

I believe Hindley, of York, was the first to employ the tangent-screw as a means of obtaining slight angular motion in astronomical instruments, and mention is made of an equatorial mounting, having this appliance, made by him.

Troughton also invented a dividing-engine, and I trust some reader will send an account of the method he adopted, of dividing the great wheel into precisely equal parts. Ramsden's method being a tentative one, is long and laborious, and must soon have been supplanted by other and more direct means of obtaining the same result.

FIG. 1

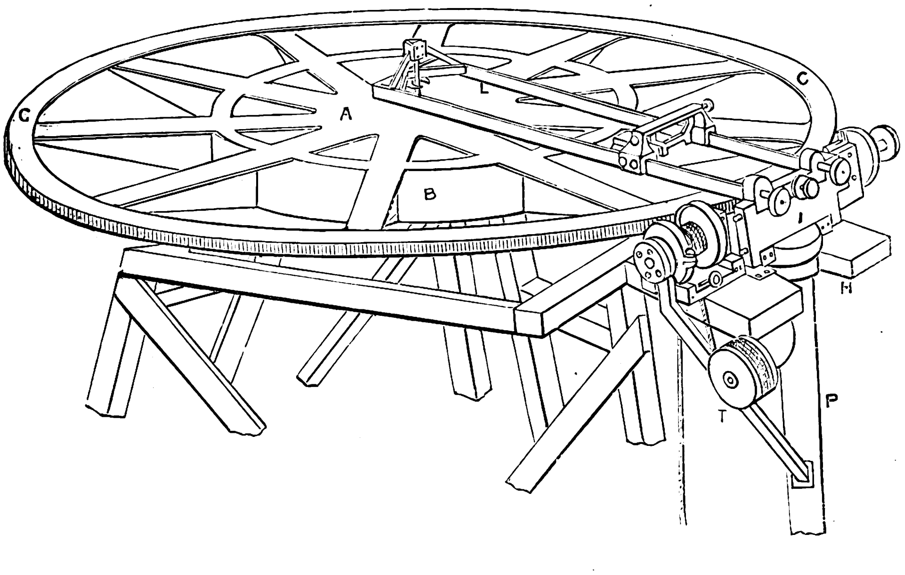


FIG. 3

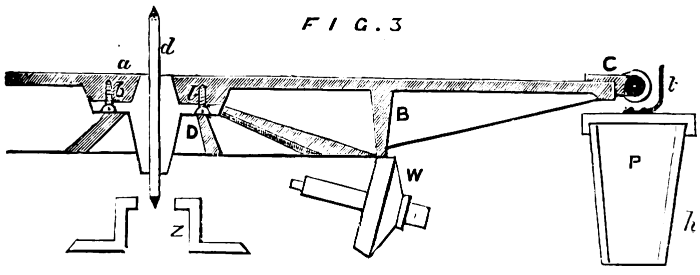

FIG. 4

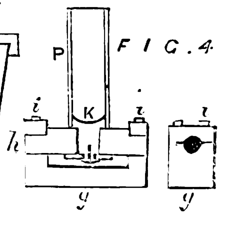
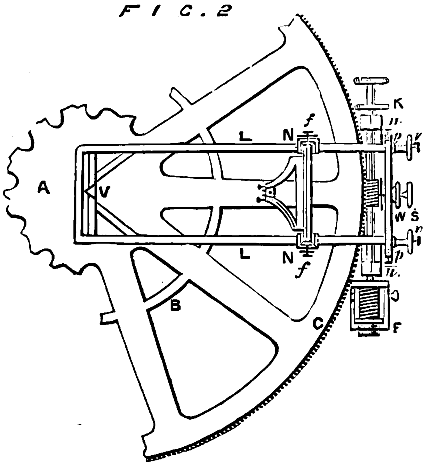


The following description of Ramsden's circular dividing-engine is copied from Dr. Gregory's "Treatise on Mechanics." The original drawings, together with other information, will be found in Rees' "Cyclopædia."

On discovering the method of constructing this machine, its inventor, Mr. Jesse Ramsden, received £615 from the Commissioners of Longitude, engaging himself to instruct a certain number of persons, not exceeding ten, in the method of making and using this machine, from the 28th Oct., 1775, to 28th Oct., 1777, also binding himself to divide all octants and sextants by the same engine, at the rate of 3s. for each octant, and 6s. for each brass sextant, with Nonius's divisions to half-minutes, for as long time as the Commissioners should think proper to let the engine remain in his possession. Of this sum of £615 paid to Mr. Ramsden, £300 was given to him, as a reward for the improvement made by him in discovering the engine, and the remaining £315 for his giving up the property of it to the Commissioners. The following description of the engine is that given upon oath by Mr. Ramsden himself:—

FIG. 2



"This engine consists of a large wheel of bell-metal, supported on a mahogany stand by three legs, which are strongly connected together by braces, so as to make it perfectly steady. On each leg of the stand is placed a conical position pulley, whereon the dividing wheel rests; to prevent the wheel from sliding off the friction pulleys, the bell-metal centre under it turns in a socket on the top of the stand.

"The circumference of the wheel is ratched or cut (by a method which will be explained hereafter) into 2,160 teeth, in which an endless screw acts. Six revolutions of the screw will move the wheel a space equal to one degree. Now a circle of brass being fixed on the screw arbor, having its circumference divided into sixty parts, each division will consequently amount to a motion of the wheel of ten sec., six of these will be equal to a minute, &c.

"Several different arbors of tempered steel, are truly ground into the socket in the centre of the wheel. The upper parts of the arbors that stand upon the plane, are turned of various sizes to suit the centres of different pieces of work to be divided.

"When any instrument is to be divided, the centre of it is very exactly fitted on one of these arbors, and the instrument is fixed down to the plane of the dividing wheel, by means of screws which fit into holes, made in the radii of the wheel for that purpose.

"The instrument being thus fitted on the plane of the wheel, the frame which carries the dividing part is connected at one end by finger screws with the frame which carries the endless screw, while the other end embraces that part of the steel arbor, which stands above the instrument to be divided, by an angular notch in a piece of hardened steel; by this means both ends of the frame are kept perfectly steady and free from any shake.

"The frame carrying the dividing point or tracer, is made to slide on the frame which carries the endless screw, to any distance from the centre of the wheel, as the radius of the instrument to be divided may require; and may be there fastened, by tightening two clumps, and the dividing point or tracer being connected by the double-jointed frame, admits a free and easy motion towards or from the centre, for cutting the divisions without any lateral shake.

"From what has been said, it appears that an instrument thus fitted on the dividing wheel, may be moved to any angle, by the screw and dividing circle on its arbor; and that this angle may be marked on the limb of the instrument, with the greatest exactness, by the dividing point or tracer, which can only move in a direct line tending to the centre; and is altogether freed from the inconvenience that attends cutting by means of a straight edge. This method of drawing lines will also prevent any error that might arise, from an expansion or contraction of the metal during the time of dividing.

"The screw frame is fixed on the top of a conical pillar, which turns freely round its axis, and also moves freely towards or from the centre of the wheel; so that the screw-frame may be entirely guided by the frame, which connects it with the centre; by this means any eccentricity of the wheel and the arbor, would not produce any error in the dividing, and by a particular contrivance (which will be described hereafter), the screw, when pressed against the teeth of the wheel, always moves parallel to itself, so that a line joining the centre of the arbor, and the tracer continued, will always make equal angles with the screw. Fig. 1 represents a perspective view of the engine. Fig. 2 is a plan, of which Fig. 3 represents a section on the line (xy). x and y are points on a horizontal line passing through the centre of Fig. 2.

"The large wheel A is 45in. in diameter, and has ten radii, each being supported by edge bars, as represented in Fig. 3. These bars and radii are connected by a circular ring, B, 24in. diameter and 3in. deep; and for greater strength the whole is cast in one piece of bell-metal.

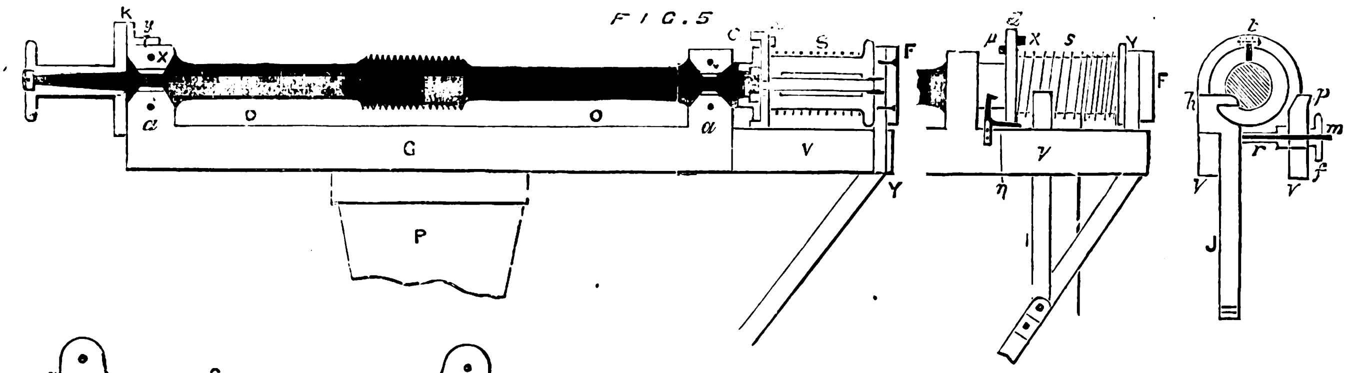
"As the whole weight of the wheel rests on its ring B, the edge bars are deepest where they join it, and from thence their depth diminishes both towards the centre and circumference, as represented in Fig. 3.

"The surface of the wheel A is turned very flat and true, and its circumference turned true. The ring C, of fine brass, was fitted very exactly on the circumference of the wheel, and was fastened thereon with screws, which, after being screwed as tight as possible, were well riveted. The face of a large chuck being turned very true and flat in a lathe, the flattened surface (a, Fig. 3) of the wheel is fastened against it with holdfasts, and the two surfaces and circumference of the ring C, a hole through the centre, and plane part round it (b), and the lower edge of the ring B, were turned at the same time. D is a piece of hard bell-metal, having a hole which receives the steel arbor (d), made very straight and true. This bell-metal was turned very true on an arbor, and the face which rests on the wheel at b was turned very flat, so that the steel arbor (d) might stand perpendicular to the plane of the wheel; this bell-metal was fastened to the wheel by six steel screws (Z).

"A brass socket, Z, is fastened in the centre of the mahogany stand, and receives the lower part of the bell-metal piece, D; being made to touch the bell-metal in a narrow part near the mouth, to prevent any obliquity of the wheel from bending the arbor: good fitting is by no means necessary here, since any shake in the socket will produce no bad effect, as will appear hereafter, when we describe the cutting-frame.

"The wheel was then put on its stand, the lower edge of the ring B, Fig. 1, 2, 3, resting on the circumference of these conical friction pulleys W, to facilitate its motion round its centre. The axis of one of these pulleys is in a line joining the centre of the wheel and the middle of the endless

FIG. 5



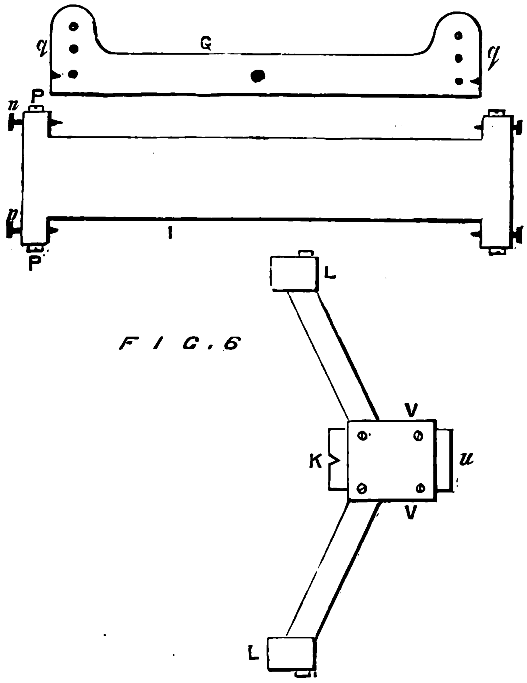


FIG. 6

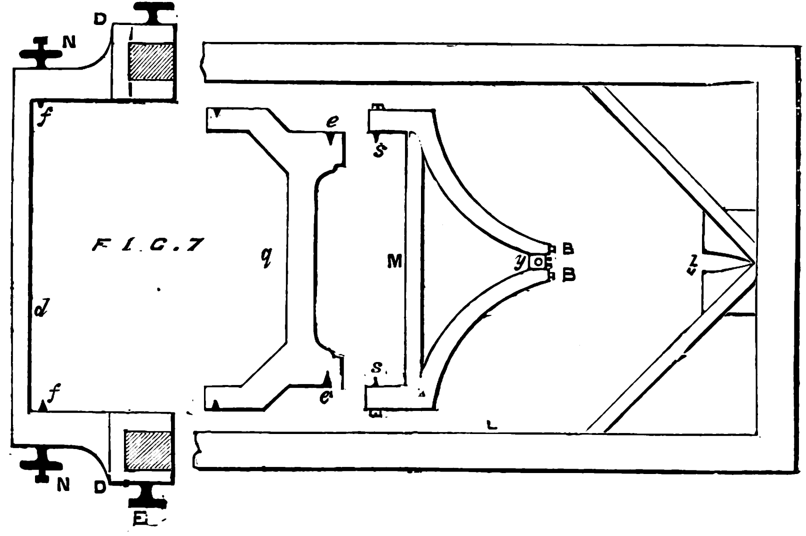

FIG. 7

screw, and the other two placed so as to be at equal distances from each other.

"Fig. 1, F, is a block of wood, strongly fastened to one of the legs of the stand; the piece *g* is secured to the upper side of the block, and has half-holes, in which the transverse axis *h* (Fig. 4), turns; the half-holes are kept together by the screws (1.)

"The lower extremity of the conical pillar P (Fig. 1 and 4) terminates in a cylindrical steel-point K (Fig. 4), which passes through and turns in the transverse axis *h* (Fig. 4), and is confined by a cheek and screw.

"To the upper end of the conical pillar is fastened the frame G (Figs. 2 and 4), in which the endless screw turns; the pivots of the screw are formed in the manner of two frustums of cones, joined by a cylinder, as represented at X (Fig. 5). These pivots are confined between half-holes, which press only on the conical parts, and do not touch the cylindrical parts; the half-holes are kept together by screws (*a*), which may be tightenend at any time, to prevent the screw from shaking in the frame.

"On the screw arbor is a small wheel of brass K (1, 2, 4 and 5), having its outside edge divided into 60 parts, and marked at every 6th division, 1, 2, and to 10. The motion of this wheel is shown by the index *y* (4 and 5) in the screw-frame G.

"H (Fig. 1) represents a part of the stand, having a parallel slit in the direction towards the centre of the wheel, large enough to receive the upper part of the conical, perpendicular pillar P, which carries the screw and its frame; and as the resistance, when the wheel is moved by the endless screw, to against the side of the slit H, which is turned to the left hand—this side of the slit is faced with brass, and the pillar is pressed against it by a steel spring on the opposite side. By this means the pillar is strengthened and supported laterally, and yet the screw may be easily pushed from or against the circumference of the wheel, and the pillar will turn freely on its axis, to take any direction given it by the frame L.

"At each corner of the piece I (Fig. 4), are screws *n*, of tempered steel, having polished conical points. Two of them turn in conical holes in the screw-frame, near O; and the points of the other two screws turn in the holes in the piece O. The screws *p* are of steel, which, by being tightened, prevent the conical-pointed screws from moving when the frame is moved.

"L (1, 2, and 6) is a triangular piece, which serves to connect the endless screw, its frame, &c., with the centre of the wheel. Each arm of this frame is terminated by a steel screw, that may be passed through any of the holes *q*, in a piece Q, as the thickness of the work to be divided or the wheel may require, and are fastened by the finger-nuts *r* (1 and 2.)

"At the other end of this frame is a flat piece of tempered steel, (*b*), in which is an angular notch. When the endless screw is pressed against the teeth of the circumference of the wheel, which may be done by turning the finger-screw, *s*, to press against the spring *t*, this notch embraces and presses against the steel arbor, *d*. This end of the frame may be raised or depressed by moving the prismatic slide *u* (Fig. 2), which may be fixed at any height by the four steel screws (*v*.)

"The bottom of this slide has a notch K (Figs. 1 and 6), whose plane is parallel to the endless screw, and by the part of the arbor, *d*, resting in this notch. This end of the frame is prevented from tilting. The screw, S, is prevented from turning by tightening the finger-screw, W.

"The teeth on the circumference of the wheel are cut by the following method:—

"Having considered what number of teeth on the circumference would be most convenient, which in this engine is 2,160, or 360 × 6, I made two screws of the same dimensions of tempered steel, in the manner hereafter described, the interval between the threads being such, as I knew by calculation, would come within the limits of what might be turned off the circumference of the wheel: one of these screws, which was intended for ratching, or cutting the teeth, was notched across the threads, so that the screw, when pressed against the edge of the wheel, and turned round, cut in the manner of a saw. Then, having a segment of a circle a little greater than 60 degrees, of about the same radius as that of the wheel, and the circumference made true, from a very fine centre, I described an arc near the edge, and set off the chord of 60 degrees on this arc. This segment was put in place of the wheel, the edge of it was ratched, and the number of revolutions and parts of the same counted between the interval of 60 degrees. The radius was corrected, in the proportion of 360 revolutions, which ought to have been made, in 60 degrees, to the number actually found; and the radius so corrected was taken in a pair of beam compasses, while the wheel was in the lathe; one foot of the compasses was put in the centre, and with the other a circle was described on the ring; then half the depth of the threads of the screw, being taken in the dividers, was set on this circle outwards, and another circle is described, cutting this part: a hollow was then turned on the edge of the wheel of the same curvature as that of the screw at the bottom of the threads; the bottom of this hollow was turned to the same radius or distance from the centre of the wheel as the outward of the two circles before mentioned."

Orderic Vital.

(*To be continued.*)

EVOLUTION—THEORY AND PRACTICE.

[19898.]—Some years ago I noticed in this journal questions were asked relating to this subject, and the answers given, as far as I remember, were limited to the square and cube roots, and that, in the rule-of-thumb sort of way, without much reference to the why and wherefore. In some arithmetics which have come under my notice a rule is given for the extraction of roots of all powers, which (dispensing with the necessity of a proper formula, as already adopted in the square and cube roots) results in a roundabout method and extra work. Let a person understanding common division, imagine the work which would be required, if at each time of annexing a new figure to the quotient, he should multiply the divisor by the whole of the quotient, and subtract from the proper part of the dividend. Such as this, by analogy, is the rule given.

Having lately given some attention to the study of this subject, I am now able to set forth a method founded on a uniform principle applicable to finding roots of all dimensions; and will endeavour to explain, also, several matters which are not referred to in the usual stereotyped rules; and this method is, I think, as simple as it is possible to find.

Instead of giving arbitrary rules, which, as a form of words, are soon forgotten, I shall appeal to the understanding by means of algebraic formulæ, showing how obtained in each case, and also their uniformity. And I think it will not be difficult to make this understood by those whose attainments extend no farther than common long division, seeing that, in the absence of negative signs, complexity is avoided. The formulæ will also be much more easily remembered than forms of words, or otherwise worked out in order to find necessary procedure, for few persons, I believe, can remember the rules usually given even for cube root.

As in common division we bring down one figure at a time, so in the square root we bring down two, and so on, according with the index of the root sought; but in order that we may commence at the right place, a system is used of putting a point over the unit's place of each period to be brought down. Thus, putting a point first over the unit's place, we, for the square root, mark over every second figure to the left, and also to the right, if there be any decimals, and so on, corresponding to the index of the root sought.

The formula showing the necessary procedure in each case may be found by taking $a + x$ as a factor, the number of times corresponding to the index of the root sought, which, worked out, gives for the square root, $a^2 + 2 ax + x^2$, cube root $a^3 \times 3 a^2x + 3 ax^2 + x^3$ biquadrate $r . a^4 + 4 a^3x + 6 a^2x^2 + 4 ax^3 + x^4$, and the fifth root $a^5 + 5 a^4x + 10 a^3x^2 + 10 a^2x^3 + 5 ax^4 + x^5$, which last is as far as I need go, as the principles are evident for higher powers. But this information would be of little use, even to an algebraist, without understanding how the terms (minus the first term) are to be placed in order to be added, so as to make a divisor, which is to be multiplied by the new root figure to produce the subtrahend. Now, if we take each term of any formula specified as above, beginning at the right, and place them in the order—units, tens, &c.—it is correct; but then, as each term often consists of several figures (when found) it would overlap the term to its left. In order to rectify this, the use of a formula of cyphers is adopted, and the terms added for a total divisor; thus:

Square.	Cube.	Biquadrate.	5th.
0	00	000	0000
	0	00	000
		0	00
			0

and the last term to the right, under the unit's place. In order, therefore, to proceed correctly, it is advisable to place in the divisor's place the formula of cyphers, which may be indicated, ready to annex to the left each term as worked in figures, not forgetting the last term to be under the last 0.

But algebraic formulæ (minus first term) here shown, if worked out into figures, would produce the subtrahend. But in order to somewhat contract the working, and to have a divisor (as in common division) with which to compare the remainder so as not to exceed, it is better to minimise the formula by dividing it by the x^1 the symbol of the new root figure; so then our divisors will stand thus. (It is better, however, to say here, that the 1st term is not again wanted after the first remainder is found, in fact done with).

$$\begin{array}{l} 2a + x \\ 3a^2 + 3\,ax + x^2 \\ 4a^3 + 6\,a^2x + 4\,ax^2 + x^3 \\ 5a^4 + 10\,a^3x + 10\,a^2x^2 + 5\,ax^3 + x^4 \end{array}$$

Which, when worked into figures in each respective case, is the sum of every divisor throughout, which × by the new root figure gives the subtrahend.

It is now time to explain what is meant by the a and the x. Now, as is usual, a means a known quantity, and x an unknown quantity, for a in the first place is the result of a table of powers, obtained either from memory or otherwise, and when subtracted from the 1st period, as said before, the first term is done with. In the 2nd place, a is to be always understood as the whole of the root or quotient found; and x is the new root figure annexed, or to be in the quotient. But before we find this we make use of a somewhat blind guide—namely (after annexing the next period to the remainder), the trial divisor, which is the commencing term of the respective formula to be used, as last shown. Having from this estimated a new quotient figure which we think to be satisfactory, we complete our divisor as per formula; we add up, and multiply by quotient figure for subtrahend, get our remainder, and proceed as before if more periods are there. In common division, there is the whole divisor to estimate from, but in evolution, only part of it—the known part. By a mental calculation of the next term, and thus by adding materially to the trial divisor (using the provisional new figure) more certainty would result.

There is, however, another blind guide—the remainder; but examples following will make this better understood.

		Trial divisors.	Into.	Appears to be.	Divisor complete.	Remainder.
$\surd$	360	20	260	83	28	36
$^3\surd$	6,858	300	5,858	19	604	1,026
$^4\surd$	130,320	4,000	120,320	30	11,872	25,344
$^5\surd$	2,476,098	50,000	2,376,398	47	223,696	586,530

Here, in each case, where we know that the quotient is 18, &c., yet instead of 8 we get 13, 19, 30, and 47 times, where we must not have more than 9; and again, the remainders are from about 1¼ to 2½ times as much as the divisor. Thus we are completely at sea as to the sufficient new root figure; but perhaps there may be a genius among our readers who could enlighten us with a method of getting over this difficulty.

I will now conclude with an example to the 5th root worked out; and in addition to the foregoing explanations it may be necessary to tell some of your readers that the numbers and letters in the formulæ separated from other groups by × mean that the numbers represented thereby are to be multiplied together, and that the small figures just above the a and x mean also the number of times they are to be factors therein. The usual method of the square root is *essentially* the same as the formula hereinbefore given. Ex. Find the 5th root of 14,348,907.

Formula. 1st subtrahend a^5; 1st divisor $5a^4 + 10a^3x + 10a^2x^2 + 5a^3x + x^4$.

$$a^5 = 2 \times 2 \times 2 \times 2 \times 2 = \begin{array}{l} 14\dot{3}4890\dot{7}\ (27 \\ 32 \\ \hline \end{array}$$

$$\begin{array}{rrr|l} 5a^4 = & 5 \times 2 \times 2 \times 2 \times 2 = & 80.0000 & 11148907 \\ 10a^3x = & 10 \times 2 \times 2 \times 2 \times 7 = & 560.000 & \\ 10a^3x^2 = & 10 \times 2 \times 2 \times 7 \times 7 = & 1960.00 & \\ 5ax^3 = & 5 \times 2 \times 7 \times 7 \times 7 = & 3430.0 & \\ a^4 = & 7 \times 7 \times 7 \times 7 = & 2401 & \\ \hline \end{array}$$

$$7 \times 1592701 = 11148907$$

Barry-road, S.E. **J. H. Huxley.**

MEDICAL REPLIES.

[19899.]—FLAT FEET, BOW LEGS, KNOCK KNEES, AND WEAK ANKLES (46382), is a comprehensive query, which I can only deal with in mere outline. As to flat feet, these are due either to congenital imperfection of the bony arch of the feet, or undue standing upon the feet, and permanent straining of the girder-like ligaments by which the base of the bony arch of the foot is kept together. In either case, flat feet is an incurable infirmity, and one that must be borne with. The policy of such a sufferer is not to aspire to become a postman, or to take up any other life which requires good feet. If he does he will always be getting lame and incurring suffering. Such a man should become a shoemaker, a tailor, or if he have the brains or education to take up a higher walk in life, he may become a wood-carver, an engraver, or other sedentary occupation, in which there is larger scope for an able man to rise.

KNOCK KNEES is due sometimes to congenital deformity of the bones which form the knee-joint, sometimes to mere weakness of the internal lateral ligaments of the knee-joint. The application of a splint, or jointed iron bar support, to the outer part of the knee, so as to keep the knees straight and take the strain off the internal lateral ligaments of the joint, is here the remedy. Sometimes we use a plaster and bandage casing for the knees, the plaster being put on wet, and the limbs held straight till the plaster has firmly set. The child then has either to be kept off its feet, or to walk with stiff knees for a time. Various expedients of this kind are indeed used to keep the knees from yielding inwards while the child is growing, but their selection and their practical application can only be advised upon seeing the case, and the applications need to be seen to be understood. Growing children, in such cases, should always be kept off their feet as much as possible, and especial care should be given to the construction of their boots. Low laced-up shoes, with square toes, broad treads, and very low, broad, vertical heels are essential. Weak ankles are due either to flat feet or to a relaxed condition of the internal lateral ligaments of the ankle-joint, and previous remarks apply.

BOW-LEGS are sometimes due to conditions of the knee-joints analogous to those causing knock-knees, but on the outer side instead of on the inner side. But in some of these cases the bones of the limbs are bent; sometimes the thigh-bones are curved too much, sometimes the leg-bones are curved, sometimes both. Here the treatment is preventive and remedial. Preventive treatment resolves itself into keeping the child off its feet, or giving mechanical support to the bones so as to prevent further yielding. Remedial treatment consists in giving the child such food as will supply earthy matters to stiffen the bones more rapidly. Here again we come back to feeding these children upon oatmeal porridge and milk. In these cases, unless there be some rare constitutional defect, the disease is generally due to the fact that during pregnancy and nursing the mother lived too largely upon meat and beer, and too little upon vegetable food, milk, and breadstuffs, such as brown bread and oatmeal, &c. The result is shown in the softening of the mother's teeth by absorption of the earthy constituents while the baby dependent upon her has its bony framework forming; also by the fact that the child's bony framework is not sufficiently consolidated by earthy matters, and therefore remains in the gristle stage so late that the leg bones bend under the action of the muscles and under the weight of the body. Under the tension of the respiratory muscles also the ribs bend, lose their curve, and the chest flattens, or the patient becomes permanently "pigeon-breasted." Of course other hygienic conditions must be attended to.

SKIN DISEASE—PSORIASIS (46429).—"Marine Engineer" will do well to live largely upon fresh vegetable diet and fruit, to avoid getting over-fat. Local applications are of little use, but a mere patch may sometimes be benefited by wearing over the skin a thin sheet of indiarubber or gutta-percha, or other waterproof material. This relieves the eruption for a time, certainly, but I am inclined to think that the amendment is not permanent. A little creasote ointment (vaseline, 15 parts; pure creasote, 1 part, and thoroughly incorporated), may also be applied, as cold cream would be used for an irritable face. Internal remedies there are which exert a large and more or less permanent control over the disease. But they are powerful and poisonous, and cannot safely be prescribed unless upon personal examination of the patient. "Marine Engineer" may safely try a vegetarian diet. What has been said about milk is not reliable.

MARRIAGE (43435).—The question of health before marriage is one of which the importance is very inadequately realised. "Widower" asks whether a woman aged 25, "who has suffered from pleurisy and sore throat," is eligible as a wife. The sore throat, if an ordinary one, and not of the nature of ulceration of the windpipe, may safely be ignored as not indicative of constitutional weakness. "Pleurisy" is another matter, but in its forecast depending altogether upon the accuracy of the diagnosis. Some people call a mere pain in the side, due to neuralgia, or temporary weakness, "a pleurisy." Rheumatism of the muscles of the side, again, is often called "pleurisy." Real pleurisy is inflammation of the lining membrane of the chest-wall and of the covering of the lung, and it is serious—generally it is indicative of lung-disease. If the woman is of good weight in proportion to her height, not short-breathed on going upstairs, and a good sturdy walker, not easily fatigued, she is not likely to have lung-disease or other constitutional delicacy. If over fat, that is not good. But here, again, the question turns upon the *diagnosis*, and this can only be safely arrived at by the skilled eye of a practical physician. People about to marry, and especially women, should always see that the spouse has passed the examination of a good life office and insured his life *at ordinary rates*. For the working classes the best office by far is the Government Assurance, effected through the Post-office. In this the funds are absolutely safe, they are not wasted in advertising, or in commissions to agents, and the forms were admirably drawn, under the advice of Dr. Farr.

DEAFNESS (46494).—A celebrated surgeon of the last generation, when lecturing to the students on surgery, on coming to the subject of ear-diseases used to say, "Gentlemen, there are two kinds of diseases of the ear—one that is curable by syringing and one that is not." He then went on to his next subject. I think that, speaking generally, what Lawrence used then to say is as true as ever; but patients suffering from deafness are not content to take the opinion of a good surgeon and act upon it, and which in most cases comes to this: "Let it alone." They will keep tinkering at the ear, and they will try every quack who offers assistance. "Auris" may or may not be one of those to whom I should say "Let it alone"; but I cannot say without seeing him and making my own diagnosis. I cannot help him by letter-writing.

COAL-TAR SOAPS (46533).—The only "effect" that these soaps produce is to put money into the pockets of the quacks who sell them. There is no soap better than the pure hard yellow soap. All soap and all ablutions are *cleansers*, but otherwise they are not *disinfectors*. For disinfection of the hands wash them in a weak solution of Condy's Fluid, just strong enough to be well coloured. For antiseptic purposes, use a solution (one in twenty) of carbolic acid after cleansing the hands well with soap and water, and rinsing the soap off thoroughly, as soap and carbolic acid naturally spoil each other. A cleanser is that which removes foul matter. A disinfector is that which kills or destroys its foulness, and, generally, by oxidation or other decomposition. An antiseptic is that which arrests decomposition, and so arrests foulness from arising, or from increasing.

COD-LIVER OIL (46534).—No cod-liver oil is better medicinally than that which can be bought by the pint at a really respectable fishmonger's, who knows what is what in cod-liver oil. The light-brown, dark-brown, and other advertised oils are all quackery, out of which large fortunes have been made by gulling the public, and which are, in no sense, worth the price which is put upon them.

INFANT'S FOOD (46540.)—The reason why

patented and proprietary foods for infants get so largely into vogue is generally because mothers and nurses do not know the simple cooking which is necessary to make nice foods. For babies under six months new milk, mixed with an equal bulk of boiling water and sweetened with loaf-sugar, is the best. It should be sucked out of a bottle. Absolute cleanliness at every step—from the milking of the cow to the sucking-in of the food—is essential; and when the baby is ill, it is nine cases out of ten because the mother does not know her business. The compound food mentioned by "Sigvald" would be very good after the child begins to get its teeth—say, after six months old. But I doubt whether much is gained by any special or very complex foods unless very carefully prepared and partially cooked with great accuracy on a large scale, as some of the proprietary foods are. Baked flour, well boiled to thin gruel and then mixed with an equal quantity of milk and sweetened, or fine oatmeal, or barley flour treated in the same way, are as good in a general way as anything that can be made. But if the stools are pasty, more flour is going down the child's throat than is digested; if curds of milk come away the proportion of milk must be lessened; if sourness, flatulency, and colic occur, the mother or nurse is generally a slut, and an emetic of ten grains of ipecacuanha powder in a little thin gruel should be given to empty out the foul contents of the stomach, and be followed by a little castor-oil to clear out the contents of the intestines. Meanwhile, feed the baby on barley-water, and inspect the bottles, teats, pots and pans, and other nursery arrangements, in order that a clean start may be made. Children are as often overfed as underfed. Many nurses lay a baby on its back and hold the bottle up so as to give the child no alternative but instant suffocation or over-gorging its stomach and all sorts of consequent aches and pains from surfeit.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

THE ETHOXO LIMELIGHT.

[19900.]—It gave me great pleasure to see in your issue of the 24th, Mr. Lewis Wright's valuable testimony of the merits of the ethoxo limelight. I believe I was the first to publish its use as a substitute for hydrogen gas, in a paper read before the Manchester Photographic Society, on my "Automatic Oxygen Apparatus," in which the principle used by Mr. Fisher is fully described. The only difference being that the oxygen gas for the regulation of the burner is taken from a T-piece a short distance away from the ether tank, to prevent the ether from rising into it. Mr. Wright seems to doubt the efficacy of the pulverised pumice in preventing explosions. If he had used it as often as I have the past three years, under varying conditions and circumstances, I believe he would come to the same conclusion—viz., that it is the best safeguard against explosions. I would not work without it. I have tried other materials, notably coarse emery and sand, but found they offered little or no obstruction to the passage of the flame. While on this subject, let me call attention to the safety mixed jets, so called from having a single layer of wire gauze in some part of the burner, which offers as much obstruction to the passage of flame as a sieve to the passage of water, or an open doorway to the inlet of air: such jets cannot be too strongly condemned. Valves are not much better, for if by any mishap—as, for instance, the filling of the hydrogen bag with oxygen before it has been emptied, and done for the sake of economy (such mistakes have occurred and will occur again). Now should the pressure be suddenly checked, the explosive mixture rushes down the pipes, and if a rubber or other membrane be interposed to prevent the return of gas, burns it and passes on unchecked to the bag, ending in its total demolition, if nothing worse occurs, the past season not having been, I am sorry to say, without its mishaps, Mr. Fisher himself being one of the sufferers, but trust he is recovering.

A good thing for experimental trials is an indiarubber balloon. This should be filled with the mixed gas as it issues from the nozzles, after it has been adjusted to give the best light, afterwards attaching it to one of the taps. So long as the pressure is kept up by the contraction of the indiarubber it burns all right; but when the balloon gets exhausted, the explosive velocity being greater than the pressure, the light is carried back, the balloon bursting with a sharp report. Another of Mr. Wright's objections is the storage of the ether. Until the advent of gelatine plates, ether in one form or other was found on the shelves of every photographer all over the world, and is still used without any great complaints about its storage or "carriage." I have oftener heard the jumping of the stopper of the ammonia-bottle than that of the ether. I have a very simple remedy for that—viz., an indiarubber finger-stall drawn over the stopper and neck like a cap. **W. Broughton.**

CHEAP MICROSCOPES.

[19901.]—May I be permitted to revert to the question of cheap microscopes, seeing that there has been, as yet, no response in the direction mentioned in a communication which appeared in the columns of "E. M." on the 27th January last, No. 19659, p. 495? I have yet to learn that it is beyond the range of possibility to produce "a perfectly efficient" microscope-stand at a less cost than £2 10s. If we consider what has been accomplished by the Americans in the manufacture of clocks and watches, will anyone be bold enough to assert that even a first class microscope-stand is as complicated a piece of mechanism, or requires a more perfect adaptation of parts, or more accurate workmanship, than a watch or clock? Yet these are produced by machinery in almost unlimited quantities.

Surely, it is not too much to hope that some English optician will be found with sufficient enterprise to undertake the manufacture of stands and accessories for microscopes by automatic machinery—otherwise, it is very probable that by a continued observance of the conservative and restrictive policy of high prices for what is, to many, unnecessary workmanship, the Americans and other foreigners will swamp the English market with cheap microscopes as they have already done with clocks and watches.

Take, for instance, the Peep-o'-day clock, manufactured by the "Ansonia Company" of New York, U.S. It is not so very many years since, that a timekeeper, of equal excellence, would have commanded nearly as many pounds as they now cost shillings. I am afraid that English artisans would never have taken the initiative in a reform tending towards cheapness of production. In the case above mentioned, however, the loss to the English watch-trade—and I may say, to the country—must have been incalculable when we think of the tens of thousands of watches alone which have been exchanged for English gold.

It is perfectly clear that a very excellent stand for a microscope need and ought to cost but little, since the price of materials is not worth taking into consideration, and we have also seen that by the employment of suitable machinery, in other instances, the cost of production is so marvellously cheapened.

I wish to be distinctly understood that it is not by any means intended to sacrifice efficiency for the sake of economy, nor do I see any necessity for such an undesirable result, since the chief cost must now, as ever, lie in the construction of the lenses.

G. Welborn, Ph.C.

Woolsthorpe, March 28th.

TOLMAN'S BATTERY.

[19902.]—With all due respect for Mr. Tolman's improved sal-ammoniac cell, permit me to state that that form of battery has been known to electricians for 15 or 16 years, and was the first form of the Leclanché, which depends for its E.M.F. upon the reduction of the salts of ammonia into their approximate elements by electrolysis.

The chlorine, uniting with the zinc, and the ammonia, being liberated, is absorbed by the water; now if this cell has any great demand upon its energy, particularly as it is pretty well sealed, the ammonia cannot escape, and it soon becomes polarised; but if that gas, at the moment of its liberation, met with an element able to decompose it, then the energy of the cell would be prolonged. This the peroxide of manganese supplies, giving up an equivalent of oxygen which unites with the hydrogen of the ammonia forming water; and if the cell is allowed sufficient time to rest between its action, the manganese abstracts oxygen from the air ready to give up when next called upon. The reason of the cell becoming at all polarised is that the sal-ammoniac is more readily decomposed than the manganese. When a substance is found to substitute the manganese, and give up its oxygen at the same rate as the decomposition of the sal-ammoniac, we shall have a splendid battery. I admire the ingenious construction of the cell, dispensing with the porous pot and allowing a good passage for the current; but must protest against the exclusion of so important a factor as the manganese.

W. Haines (Firm of Newton and Co.)

MR. BENNETT'S BATTERY—GRATIS ADVERTISEMENTS.

[19903.]—I thank "Os," Mr. Soward, and Mr. Horton for their replies to my query regarding soda. I quite understand that Mr. Bennett's paper did not say that "potassium hydroxide" and soda were the same thing; but I think to any beginner ignorant of chemistry it may imply as much. It would be much better if all chemicals, &c., likely to be used by beginners, where there would be no likelihood of a mistake, were called by their commercial names.

It may interest some readers to know that the porous cell can be dispensed with.

I have some cells made up in teacups, with a tin partition across the middle, cut so as to be a fair fit, so as not to allow small chips to pass and perforated with a few small holes. The partition may form the negative plate; but I prefer a negative plate, parallel with the partition and midway between it and the side of the cup, packed with turnings between the cup and it, and it and the partition. The positive plate is a bit of sheet-zinc hooked over the side of the cup and reaching to the bottom. (Of course it must be kept carefully from touching the partition.) The cup is half-filled with solution. One of these will ring my bell for one hour and a half continuously, and will regain its normal strength in about an hour. I have not found any difficulty from having the positive side open to the air, neither of my cells being closed.

I have noticed that cells made up on this plan will not start work as quickly as with a porous cell on Mr. Bennett's original plan.

I must say that "Os" has expressed the sentiments of all our readers whom I know, as to Mr. Chaster's letter on p. 61. He ought certainly to send a description of his battery, not merely an advertisement. **W. W. H. G.**

[19904.]—I have had a good deal of experience some time ago with battery cells, and appreciate their improvement very much. Now Mr. Bennett's discovery may be regarded as the distinct root of all future battery cells. I think they may be used almost for every purpose for which voltaic cells are used, depending on the number of elements and arrangement for the various purposes required.

I have tried one of these cells this week (ending 1st April), and I am highly gratified with it; and I have made a modification of it, which will almost make it cheaper. My plan is identical with the Bennett cell, except that I substitute carbon or coke (broken to the size of beans and peas) for the iron borings, with equal satisfaction. This modification is all open at present, but I intend to have an air-tight stopper on the porous pot. The liquid has subsided more than an inch in eighteen hours, which a stopper would prevent. I believe they are stronger when open; but of course they won't be so durable. One cell will produce a shock, with an ordinary size coil (shocking coil), lasting many hours; but the ultimate duration of these cells has yet to be ascertained, and Mr. Bennett's announcement of that will be universally welcomed by the readers of "ours."

South Shields. **J. H. Anderson.**

SCREWDRIVERS.

[19905.]—Sir Edmund Beckett's paper on screwdrivers puts me in mind of a circumstance which occurred with me nearly 30 years since. It was at the close of the General Exhibition in Cork in the year 1852.

The late Mr. John Kennan, the well-known engineer in Fishamble-street, Dublin, was packing up a very beautiful lathe which he had exhibited; he was on his knees screwing down the cover of the case with a *screwdriver set in a brace*. I was standing by him, when he turned up his good-humoured face and said, "That, Mr. Lecky, is the only machine I have ever known in which increase of power is accompanied by increase of speed"! You will easily perceive the drollery of his remark.

1st April. **Robt. J. Lecky.**

COMBINED ELLIPSE AND ECCENTRIC CHUCK.

[19906.]—A practical plan I have seen tried for this has been to make the piece that keeps the leading screw of the eccentric chuck from endway motion, instead of being, as usual, attached by screws, to turn on a pivot, so that by turning it back, the screw is free and can be withdrawn, leaving the slider free to traverse under the guidance of the ring and bars proper to the ellipse chuck. Another way is to make the nut of the slider to attach to it by a screw (or two), as the leading nuts of ornamental sliderests are. This screw, or screws, can be withdrawn by a thin turnscrew, inserted by a hole through the nose of the chuck.

Treadle.

LATHES AND LATHE-MAKING.

[19907.]—"J. K. P." wishes always to be courteous, and is sorry to see, by "Scorpio's" letter (12877), that he has failed in being courteous by "guessing at" something that he cannot understand. "J. K. P." is not aware that he did guess at anything; there was no guessing required. Now, speaking in the first person, I ("J. K. P.") say that I did not understand "Scorpio's" "notation," and I did not use the word "nomenclature" at all. And I have some reason to believe that "notation" means the form in which an equation or mathematical formula is expressed, and as "Scorpio" himself says the formula that he supplied was mutilated by the man who composed his letter, No. 19819, he need not have got his raiment so very much rent on that point. It appears that "Scorpio" has taken the two words "notation" and "vernacular," both of which appear in my letter on p. 55, and out of them has evolved "nomenclature," which he pretends to quote as mine.

As to Whitworth's plan of rounding-off the threads being "slovenly," or the "certain *lathe-screws* USED for ornamental turning," &c., &c., in "Scorpio's" letter, I beg to say that I have been cutting screws for 40 years, and that I never, in the whole course of my experience, saw a screw cut by any one else, or still less (except once) cut one myself that did not at least "profess" to be rounded off to a greater or less extent. That one unfortunate exception I remember to this day with remorse.

What on earth are "Scorpio's" "unavoidable inequalities"?

As to "analogy" between trigonometry and poetry, I don't see the need of supposing such to exist. I merely said I could not understand a poem any better than I could "Scorpio's" formula. Acknowledging humbly, as I do, my ignorance or want of appreciative power, I am said to lack "courtesy," forsooth! Must I go further still, and tell "Scorpio" that by "shop" I mean *work-shop?* And, further still, to tell him that almost all lathes, except those made by Holtzapffel & Co., or by such makers as copy H. and Co.'s tools, have *Whitworth's* threads on their mandrels, as *e.g.*: plain, ungeared, 5in. lathes, ⅞in. diameter, nine threads to an inch; geared 5in. lathe, 1in. diameter, eight to an inch: 5½in. geared, 1⅛in. diameter, seven to an inch; 6in. geared, 1¼in. diameter, seven to an inch, and so on. As a practical man, I should never dream of putting anything but a Whitworth thread on a new lathe-mandrel. Save and except that, I have often thought, and do now believe, that a very much coarser thread would be better still; say, for 1in. nose, six, or even so low as four, threads to the inch, and the nose itself not more than ¾in. long. But this is verging on the heretical and chimerical, so I forbear.

J. K. P.

UNIVERSAL CUTTER.

[19908.]—I NOW give a description of an instrument which sometimes is called a "fly-cutter," and sometimes a "universal cutter." It is very easily made, and is capable of doing very beautiful work. The one I am describing, and which I have made for my own use, I only work in two positions, vertical and horizontal, and though I have seen descriptions in books of instruments somewhat similar, but made to work at intermediate angles to mine, I never saw any advantage in it, and they are much more complicated. Fig. 1 is a general view; the head or frame A B C is of gunmetal cast in one piece. The part A, which carries the mandrel, is 1in. long by ⅞in. diameter, and is cylindrical; the mandrel is of steel, and has a round boss D at one end, having a square hole through it, into which fits the tool G, which is secured by the set-screw H, which has a squared head for a small spanner. This square hole or tool-holder must be made so that the centre of the tool is in a line with the centre of the square shank I, so that, no matter whether the instrument is set vertically or horizontally, the tool will still be in a line with the centre of lathe mandrel. The dotted lines show the shape of steel mandrel and how it is coned to compensate for wear, and of course, A is bored out to correspond, and the two are nicely ground together. Over the other end of mandrel a steel pulley, E, is slipped and made to revolve together by a feather, and at F are two lock-nuts, by which the wear can be taken up; there is an oil-hole in centre of A, as shown. At C the casting is bored to fit tightly on the rounded end of shank I, and both casting and shank are then drilled through and pinned as shown at C, and must be placed so that when I is in tool-holder of slide-rest, according to which side the shank is placed on, so the mandrel of instrument will either be truly horizontal or vertical. The shank I is ⅝in. square. When used horizontally, the gut-band from overhead passes directly round the grooved pulley E; but when used vertically, after passing round F, the band must go round the two guide-pulleys K K. A side view of these guide-pulleys, and their mode of attachment to frame, is given in Fig. 2. The pulleys are secured to an iron boss, L, by two screws, which also serve as axles; and the boss has a shank M, which screws into the frame B Fig. 1, so that the guide-pulleys, with their boss, can be readily unscrewed and removed at pleasure. Fig. 3 shows the shape of the tools used in instrument. The four in bracket are a front view, and the fifth a side view. The tool shown in tool-holder is generally made in three or four widths at cutting end. These tools are 1in. long, by ¼in. by ⅜in. shank. With this instrument, such work can be done as plain fluting of different widths; what is called the basket pattern, either straight or spiral; also straight line patterns on flat surfaces, such as the lid of a snuffbox; and this is also the best tool to use, set vertically, in beading or fluting irregular-shaped articles in combination with the curvilinear apparatus. Also the geometric staircase, which is very beautiful, can best be done with it; and as Mr. Evans explains how it may be done with the eccentric chuck, in the number for March 3rd, I shall give a short account of how I have executed the same pattern with this instrument. First turn the stem of your vase, or whatever the article is, cylindrically between centres of lathe; set your slide-rest with this instrument in tool-holder, parallel to work, with the mandrel of it horizontal, and a tool similar to the one shown at G of whatever width you wish the steps of your stairs to be. Throw off the band of your lathe, and put the overhead gut in its place around the pulley E. Place the counting index point in first hole of circle on dividing-plate of lathe, and beginning at one end of work, make the first cut straight into the centre of cylinder, which, if it is of any length, will require a back steady to support it. For the next cut, move main slide of rest as many degrees of its scale as are equal to the width of tool used, and move the index as many holes on dividing-plate of lathe as will give the spiral required, whether a quick or slow one, and take a second cut to the same depth as first; and so on, making the same movements between each cut until the stairs are complete. I often make it double or treble if the cylinder is of any thickness, and to do this you move back the slide of rest to where it commenced, then place index point at the half or third of circle, according as you want a double or treble spiral, and proceed as before. I think anyone will say there is less risk of injury to the work by accident in this mode than Mr. Evans's, and besides, the cutter revolving so much quicker, leaves a cleaner cut than with a fixed tool and the eccentric chuck. Another way in which I have sometimes varied this pattern is, previous to cutting the steps, to bore out the cylinder its entire length, and after the steps are cut, to insert a rod turned to fit the bore, of ebony, say, in an ivory staircase, or an ivory rod in an ebony staircase, and the contrast is very pleasing.

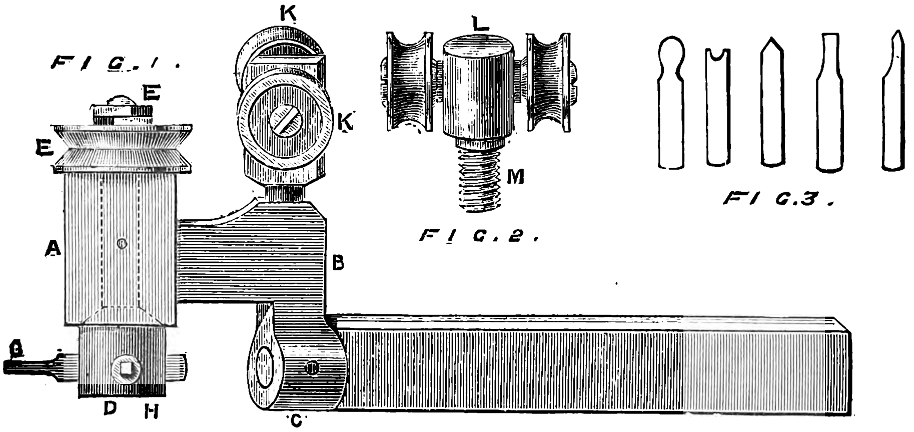

FIG. 1. FIG. 2. FIG. 3.

In using the universal cutter, you must feed it very gently, and keep the tool sharp, and drive it quickly; otherwise, in consequence of the necessarily small size of the pulley E, only 1in., the band will slip and the tool catch in the work, though it never does any damage, such as a fixed tool in the slide-rest would do if it were to "catch in."

F. W. G.

HUXLEY'S CALCULATING MACHINE.

[19909.]—THE machine for calculations illustrated on page 56, ENGLISH MECHANIC, is novel and ingenious, but the description fails to convey to your readers that its utility is likely to equal that of a well-arranged straight slide-rule. In such calculations as, say, the cost of 11cwt. 1qr. 17lb., 13cwt. 2qr. 19lb., 17cwt. 3qr. 13lb. at 17s. 7d. per ton, the latter instrument giving the respective values 120, 144, 188 pence, each within one halfpenny of correct, all at a single setting, and each operation and result being left undisturbed and open for revision (when necessary, at least); but by the proposed machine, for same examples, the cwts. or qrs. in a ton on arm G having been adjusted to the price 17s. 7d. on arm F, the arms B C require to be pressed together or opened for each calculation, so each operation on B C, but last, has to be disturbed, and consequently is beyond revision unless by re-setting. And, further, as by the straight rule, square and cube powers and roots are obtainable at sight, and such calculations as $\sqrt{5\cdot5^3/11 \times 53/37 \times 17}$ give 19·2, answer, very nearly, at one setting. A careful consideration of the two systems, viz., by proposed and straight instrument, is important.

March 28th. **Buttershaw.**

GRESHAM'S AUTOMATIC VACUUM BRAKE.

[19910.]—I HAVE noticed lately several queries in the ENGLISH MECHANIC relating to the automatic vacuum brake on the L. and S.W.R. I have prepared a short description of it with a rough diagram, which I trust you will insert, if you can afford the space, feeling sure it will be of interest.

Gresham's automatic vacuum brake is a modified form of Smith's automatic vacuum brake, and has been tried on the G.N. and L. and N.W. railways. It has also been fitted to the new L. and S.W.R. rolling stock. Its action is as follows:—

Before starting, the driver creates a vacuum with the large ejector on the engine in the train pipe, and also in the vacuum reservoirs (R), in connection therewith, which are under each carriage. Whilst running, the vacuum is maintained by the small ejector until the brakes are required for use, when air is admitted to the pipes, and the brakes are applied.

FIG. 1.

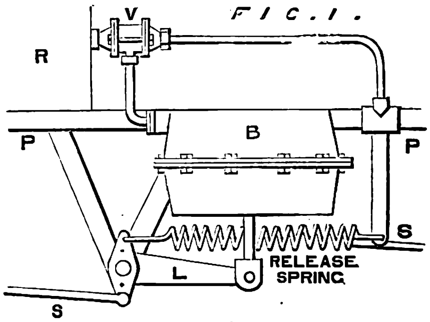

FIG. 2.

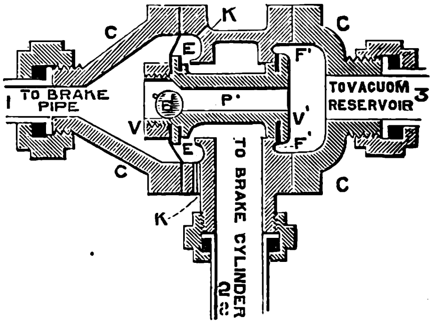

Under each carriage is fixed a patent valve V (Fig. 1), which is connected with the reservoir R, the Hardy brake cylinder B, and the train-pipe P, a passage being also provided to the atmosphere. Whilst the vacuum is maintained in the train pipe the main valve V (Fig. 2) is drawn into the position shown, and the rubber faces F′ are pressed against the seatings in valve-casing C. The pressure of the atmosphere entering at K and acting on the diaphragm D serves to keep the valve in this position. It will be seen that all communication between the brake cylinder B and vacuum reservoir R is effectually cut off, while the brake cylinder is in free communication with the atmosphere, and the blocks are kept clear of the wheels. At the same time the ball-valve B′ is unseated, leaving a free passage P′ through the main valve V′ between the main pipe and the reservoir, and the vacuum is maintained in the latter. When the vacuum is destroyed in the main pipe P, either by the driver, guards, or by accident, the pressure on D forces it and the valve V' over; the rubber faces F seat themselves, and those marked F' are unseated. Meanwhile, the valve or ball B' has been seated, preventing the destruction of the vacuum in the reservoir. In the position as above described, the main valve V' cuts off all communication between the atmosphere and the brake cylinder, and, owing to F' being unseated, the vacuum in reservoir R draws out the air from the brake cylinder. The leather diaphragm in brake cylinder is forced up, and the piston-rod draws up lever L, carrying with it the rocking shaft, and consequently the rods which pull the blocks on to the wheels. To release the brake a vacuum is created in the pipes, the valve V' returns to its first position, the vacuum is destroyed in the brake cylinder, and the brakes are released. Clayton's coupling is used with this brake.

Can Mr. Stretton kindly say if the automatic or self-closing couplings for the Westinghouse brake have been condemned, as I see that all the new carriages fitted with that brake have the old-fashioned cocks at the end of each vehicle. Will he kindly say why this change has been made? If it will be of any interest, I shall be happy to send a sectional sketch of the couplings.

Centaur.

THE CONTINUOUS BRAKES RETURN.

[19911.]—THE Eighth Continuous Brakes Return (No. C 3,149) has just been issued, and the following table gives the amount of rolling stock fitted with brakes which appear to fulfil the necessary "conditions."

As upon former occasions, I have placed vehicles which are provided with connecting-pipes only in a separate column.

Statement showing the amount of Rolling-stock fitted with Continuous Brakes which appear to comply with the Conditions of the Board of Trade, December 31st, 1881.

Name of Continuous Brake.	Name of Railway Company.	Amount of Stock fitted.		Fitted with Connecting-pipes only.	Miles run by fitted train in half-year.

,, ,,	North British	96	656	245	1,122,656
,, connecting-pipes	East Coast, Joint Stock, and Cars.	..	..	121	..
	Total as above	1,465	8,535	1,997	
	Total June 30, 1881	1,132	6,881	1,224	
	Showing an increase of	333	1,654	773	

The total passenger rolling-stock consists of 5,287 engines, and 45,235 carriages and vehicles, and the table shows that only 1,465 of the engines and 8,535 of the carriages are fitted with efficient brakes.

The Great Western and Midland companies include 578 engines as fitted with the Sanders and Bolitho Vacuum brake, but the fact is they are provided with *steam brakes*, which do not fulfil the conditions, and are not self-acting in case of accident.

During the half-year twelve more Midland express engines have had the Westinghouse Driving-Wheel brake fitted to the coupled wheels. Sixty-six horse-boxes and other vehicles have, during the same period, been fitted with connecting-pipes for both the Westinghouse and Sanders brakes.

Barker's Hydraulic brake has been removed from three more Midland carriages and replaced by the Sanders and Bolitho.

The Lancashire and Yorkshire Railway Company has nineteen engines with the Westinghouse brake, but seven of these are working with trains not so fitted.

The North-Eastern have 35 goods engines provided with the Westinghouse brake to work excursion trains.

Kendall's steam brake has now become extinct, as the North-Eastern Company has removed it from the trial train of one engine and nine vehicles, and this rolling-stock will be refitted with the Westinghouse brake.

One new system appears for the first time in the present return—W. Parker Smith's automatic vacuum. It is fitted to four vehicles on the Liskeard and Caradon railway, but it can only be applied by the guard.

The following brakes are also in use, but they do not fulfil the conditions, and are, therefore, inefficient:—

Barker's Hydraulic (two systems).
Clark's chain.
Wilkin and Clark's chain.
Clark and Webb's chain.
Fay's.
Fay and Newall's.
Newall's.
Heberlein friction.
Smith's vacuum.
Parker Smith's vacuum.
Westinghouse pressure.

It is unsatisfactory to find that, during the past half-year some companies have fitted trains with inefficient brakes, which, at some future time, will have to be removed or modified, thus causing great unnecessary expense, trouble, and delay.

Clement E. Stretton.

Saxe-Coburg-street, Leicester, March 31st.

ERRATA.—P. 81, col. 2, line 70, for "mound on the foil, if iron, carefully" read "mound, on the foil, of iron carefully," P. 81, col. 3, line 34, for "base" read "box." P. 88, col. 3, line 14 from bottom, for "compound of ammonia" read "compound ammonia."

Alfred W. Soward.

AT a cost of £88,000 nearly 1,900 miles of railway have been interlocked on the London and North-Western Railway.

REPLIES TO QUERIES.

⁂ *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[34041.]—**G.N. Engines (U.Q.)**—There was a class of passenger engines introduced about the time referred to, built by Hawthorn. This class had single driving-wheels, 6ft. 6in. diameter, and leading and trailing wheels 4ft. diameter. The cylinders were 16in. diameter and 22in. stroke, boiler 10ft. by 4ft., 174 tubes, 2in. diameter; lap of valves 1⅛in., lead in full gear, 3-16in., ports 14in. long, steam ports 1¼in. broad, exhaust ports 2¾in. wide, no dome, cylinders inside. Or does querist refer to those of the Crampton type, inside cylinders and intermediate crank-shaft? They had 7ft. drivers and 16in. cylinders, stroke 20in. They were, I believe, built by E. B. Wilson, Leeds.—CARSTAIRS.

[34042.]—**G.E. Engines (U.Q.)**—The old 97—102 class, built by Stephenson, were, as "N. Z." remarks, very powerful engines considering the period when they existed. They had domes of the well-known Stephenson type, on firebox; I believe he is correct with regard to the dimensions he quotes. To these, however, I can only add the weight, which was 24½tons, of which 8tons 16cwt. rested on the leading-wheels; 10tons 15cwt. 2qrs. on the driving-wheels, and 4tons 19cwt. on the trailing-wheels.—CARSTAIRS.

[35398.]—**Jenny Lind Engines (U.Q.)**—If "R. N. H." has not yet got the required information, the following may be of service to him. These engines were used on the Midland, M.S.L., L.B. and S.C., and E.C. railways. They were built by E. B. Wilson. On the M.R. 26 and 27, on the Brighton 61 to 69, and E.C.R. Nos. 103 to 107 were of this type. They were single engines, with inside cylinders, double frames, inside bearings to driving-axles, and outside to leading and trailing; fluted dome on boiler, and safety-valve to match on firebox. The pumps were either worked by a small eccentric (outside), or by crank-pins in the bosses of the driving-wheels. They varied on different lines in minor details. All had cylinders, 15in. by 20in. stroke; driving-wheels, 6ft.; carrying-wheels, 4ft. M.R. 26 and 27 had 124 tubes, 2in. by 11ft.; heating-surface, 708 sq. ft.; firebox, 57 sq. ft.; and weight, 24 tons. The "Jenny Lind," on the M.S.L., had more firebox-surface, viz., 81 sq. ft., and grate-area, 12¼ sq. ft. Other engines of the same class had 142 tubes 2in.; heating-surface, 910 sq. ft.; firebox, 90 sq. ft.; total, 1,000 sq. ft.; boiler, 3ft. 10in. by 11ft. long. The E.C.R. "Jenny Linds" (103—107) weighed—

	tons	cwt.	qrs.
On leading-wheels	7	17	2
,, driving ,, ...	10	19	0
,, trailing ,, ...	4	0	2
Total	22	17	0

—CARSTAIRS.

[45569.]—**Velocity of Water in Sewers.**—"J. C. S. B." is in error in the result on page 571, Vol. XXXIV.; he shows a greater discharge for 18in. pipe ⅔ full than is due to 18in. pipe running full down 1 in 100. Velocity $= 55\sqrt{R \times 2H}$, $55\sqrt{\cdot436 \times 2 \times 52\cdot8} = 55 \times 6\cdot8 = 374$ft. velocity, $374 \times 1\cdot254 = 469$ cubic feet per minute.

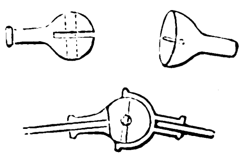
$$R = \frac{1\cdot254 = \text{area of water in pipe}}{2\cdot874 = \text{wetted circumference of pipe}} = \cdot436$$

R is the hydraulic mean depth, and in circular pipes running full is one fourth diameter, and would be $1\cdot7671 / 4\cdot712 = \cdot375$ in that case as against ·436 as above; the 18in. pipe full would have velocity 346·5ft. per minute, and discharge 610·2 cubic feet per minute.—JOHN S. B. BELL, C.E., Newcastle.

[45765.]—**Watch Jobbing (U.Q.)**—"Cranto" must enlarge his barrel holes, turn a stopping to fit, rivet in, and open to fit pivot: but this must be carefully done, or the barrel will be thrown out of flat. You omitted to mention the sort of barrel you wish to operate upon.—F. C. PUTLEY.

[45766.]—**Watch Fusee Chain (U.Q.)**—One end must form a double link, and the other a single one. To accomplish this hold the chain in the nippers in such a manner that only the part to be removed projects beyond them, the best place to hold it being across the next rivet, which is thus prevented from starting. Rest the projecting link on its edge on a piece of hard wood or bone held in the vice, and with the point of a penknife split the link open, and extract the rivet and the broken part of link. Should rivet remain behind, it may be extracted by placing it over a small hole, using the point of a needle as a punch, and a light tap with the hammer. Practise upon a large chain at first, and for rivets get a piece of chain wire from a watchmaker. Fit chain together so that both hooks point the same way.—F. C. PUTLEY.

[45864.]—**Universal Joints in Shafting.**—In the annexed sketch "Ignoramus" has sketch



asked for of the cup-and-ball joint for shaft. It is known as Keller's. The pin shown by dotted lines in left-hand half goes through the bar in the right-hand half, one of which pins merely bears against the interior wall of the shell. In another form the globular portion is kept in the hemispherical shell by means of a ring-cap bolted by its flange to a flange on the other portion. In that case friction is the only thing compelling one portion of the shaft to turn the other. I think it will be better for the querist to use four joints at angles of 15° than two at 40°.—J. T. M.

[45949.]—**Soldering.**—I am merely about to mention that for soldering anything that can be done with a lamp, there is nothing like muriate of ammonia dissolved in water; whatever has to be soldered, the solder melts just when the muriate evaporates. The wire or brass is merely wetted with it and touched with the solder, as it dries and evaporates. No cleaning is required, and no corrosion takes place, and it is seen at once when the solder will melt.—Edw. Thos. Scott.

[45990.]—**Organ Pipes (U.Q.)**—The scale of pipes in the above-named query are as follows:—CC 4in. by 3½in.; Ten. C 2in. by 1¾in., Mid. C 1¼in. by 1 1-16in.; G in Alto ½in. by ⅝in. I may here also state that the front boards of those pipes are cut across inside for height of mouth, which is one third the width of pipe.—D. W. C.

[46015.]—**Fowls.**—I see every now and then questions about their laying, and about this most people are sadly mistaken, and then complain of the fowls. You hear people say, "I get so few eggs and I give them the best barley, maize, and in extra quantity too, and the eggs don't pay the cost." Yes, and you may go on giving them barley and those kind of things, and they don't lay. People are quite mistaken. Fowls are really animal feeders; and if you want them to lay and to go on laying the greater part of the year, you must not give them too much barley, wheat, &c., but give them some animal food. Had I not done away with the account, I could have told a tale about my fowls. I always let them come into the garden when digging, or turn up some ground for them to get the worms. I collected all the snails I could get, and it is a good plan to get a sheep or bullock's liver and boil it hard, and give them a little every day. I cannot tell particulars; but we had five fowls, and from them we got above 1,500 eggs in the year, but gave them little grain food. They cannot lay properly if they don't have animal food.—Edw. Thos. Scott.

[46160.]—**Birmingham Wire Gauge.**—"Collodion" should procure from Spons, Charing Cross, the "Report of the Committee of the Society of Telegraph Engineers," price 1s., in which he will find a table of the B.W.G. according to different authorities. Mr. T. Hughes also issues, with same publishers, a pamphlet on the "English Wire Gauge," price 2s. 6d., which contains a table giving the French and German gauges. From the tables he will find that B.W.G. has no definite size to any No. of wire, but that wire of a certain No. may be some thousandths of an inch smaller or larger than the gauge by which it is measured. —Nun. Dor.

[46161.]—**Pumping to Pressure.**—If I put down a set of pumps for the high level, I should want an escape-valve in the well or in the reservoir. More information will oblige.—Water Motor.

[46180.]—**English and Norwegian Fish Guano.**—Somewhere in the Parliamentary papers there is a report from Consul Crowe on the trade and industries of Norway, but when it was issued I do not know. I am inclined to think that something similar to the following appeared in these pages some time ago, but here is an abstract of the matter. The Norwegian fish guano is made by grinding fish-offal, composed chiefly of heads and bones of the cod. The Norwegian manufacturers of Lofoden and Finma rkmake their guano almost exclusively from the heads and spines of the codfish, offal from herrings and soft parts of cod and other fish being seldom utilised for this purpose, as the expense of producing guano from the latter substance is greater and the product of an inferior quality. The manure which originally appeared for sale under the name of Norwegian fish guano was made exclusively of the first-named substances, and, according to chemical analysis, is composed of the following elements: Water, 13 per cent.; organic substances (of which 8 per cent. is nitrogen, and 7·6 per cent. ammonia), 49·3 per cent.; and inorganic substances (of which 14·9 per cent is phosphoric acid), 37·7 per cent. This larger proportion of fertilising agents has led to its being held in such high favour in the agricultural markets. It is manufactured as follows: The heads and bones of the fish are collected at the fishing-places and dried on the hills in the open air, before putrefaction sets in, the heads being tied in bundles of twenty each, and the bones carefully separated. After having been sufficiently dried, so as to be no longer exposed to the risk of putrefaction, they are carried into the manufactory, where they are cut into small pieces, thoroughly dried on plates in a kiln, and crushed; finally, the mass is ground between large millstones to the fineness of common flour. The heads and bones are crushed separately, but mixed together during the grinding process. As a rule, one sack, containing 204 pounds of bones, is mixed up with five sacks of heads; this turns out the best result. When guano is to be produced from damaged salt fish and herrings, the mode of manufacture is different, as the fish is not capable of being dried when containing salt, which must be previously removed. This is effected by means of a cylindric caldron of iron, furnished with the necessary cranes and openings for filling in and taking out the raw material; after that the cylinder is filled, steam is led into the bottom of the same from a boiler, and the mass exposed to a pressure of 30 pounds for about half an hour, sufficient to separate the salt, which runs off through a channel in the cylinder. The mass is then taken out, dried in the kiln, and crushed and ground in the manner above described. Fat is a similar hindrance to drying the raw material. When guano, therefore, is to be produced from herrings, or flesh of whales, Greenland sharks, &c., the mode of manufacture is the same as in the case of salt fish, the fat being extracted by means of steam-pressure, after which the mass is easily dried and ground. Guano of herring-heads is manufactured in the same way as cod-offal, the raw material being simply dried and ground; but this guano is of an inferior quality.—S. A. C.

[46189.]—**Muffle for Firing Painted Glass**—To "Jack of All Trades."—Many thanks. Would you add to your kindness by giving drawings and dimensions of cast-iron muffle to take 12 by 12 superficial, and with four shelves; also some idea of how to fix it in brickwork. I am not near pottery, and no fireclay to be had in locality. State distance from firebars to bottom of muffle. Also whether the flame must be in contact with bottom and all four sides?—Vitreus.

[46234.]—**Drum Timepiece.**—Some correspondents seem to be puzzled about pallets of drum timepieces, when cut, to put them in repair. This is easily done by lengthening either pivot of pallet-arbor, and putting a new bush to shift pallets either forward or backward, as required, for a new place for wheel to work on. A frequent cause of stoppage in these timepieces is the wearing of pivot above pendulum; when this is the case, it is best to make a new pivot here, and put a new bush in plate; this gives the desired result, both in pivot and escapement.—Skip.

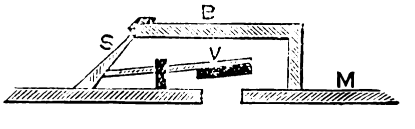
[46284.]—**L. and N.W.R. Brake Trial.**—The brake tried on the L. and N.W.R. on the 15th of February, was Gresham's modification of Smith's automatic vacuum brake. I have sent a description of it to the editor, which he will perhaps insert.—Centaur.

[46285.]—**Railway Brake Trials at Newark.**—I cannot say whether a report of these can be obtained; but "E.W. J." will find full details and much interesting information as to the engines which drew the trains, and also concerning the action of the brakes, in the *Engineer*, published immediately after (Vol. XXXIX.)—Centaur.

[46295.]—**Paralysis.**—I am very doubtful, if "C. R. B.'s" friend went to the trouble and expense of making a machine, if it would be of much use. I purchased a rotatory foot-power tricycle in May last year, thinking, at the time, I should partly regain locomotive powers. I could then walk, with the use of a stick, one or two hundred yards—not more, and I can do the same now. I can certainly drive the machine with more ease, and up a moderately stiff hill; but the only benefit I have derived from it is after doing eight or nine miles in this hilly part of Somerset, I am able to sleep better. Has "C. R. B.'s" friend ever tried Turkish baths? For my part, I think there is more benefit to be got from Turkish baths than many are aware of. Cannot Dr. Edmunds tell us how to rig up one for home use?—Hopeful.

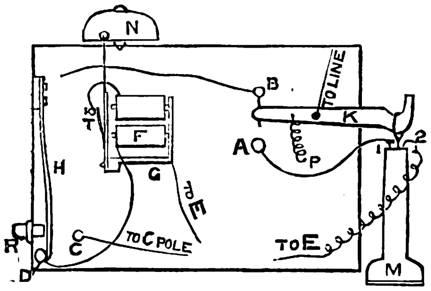
[46296.]—**Harmonium or Organ.**—Gentlemen, thanks. On suction I decide "Joiner's" rows at back, one over other with strips on underside. Soundboard appears simple and effective. Would strips affect tone? Sub-bass stands in way. Is it still possible to put complete rows at back, or must I be content with half-rows? Will "Joiner" kindly give promised hints for making the board, as it may be difficult to get two rows one over other. If doomed to half-rows, could channels be brought from sub-bass, same way, so dispensing with my present double-pallet action, which, with coupler, is stiff, and wastes wind. If practicable, how long should bass-pallets be?—Beta.

[46296.]—**Harmonium or Organ.**—The relative merits of the above instruments were discussed at great length some years ago in the Mechanic. If "Beta's" experience has not already proved to him which is the best, a revival of that discussion would hardly convince him. For my own part, I never heard from the harmonium the same rich, sonorous bass and clear ringing treble as is produced by American organ. Nor do I think it altogether due to voicing of the reeds or cavities in tubeboard, but these along with the exhaust system. Don't change to pressure bellows "Beta." If you want more power and variety, sell your organ and begin afresh with four-row tubeboard; or if the present instrument has voiced reeds and you add other two rows, let them be unvoiced. "Joiner's" sketch and mine are almost identical—viz., channels under mortice board. He shows it with a second tubeboard at back; reed apertures cut in mortice boards, with reeds screwed on over channels similar to harmonium plan, will answer. The reeds would then require covering by a sort of shallow box, the side over heel of reed hinged so as to open or close by stop. When closed, sufficient air might get in to make some reeds speak. Drain off this by inch diameter hole at each end. Over this hole must be a leather-covered valve so arranged as to be up only when stop is not drawn. See rough diag.:—M, mortice-board; B, box over reeds; V, valve inside box; S, stop-valve. Where I in "Beta's" place, I would channel underside of M, longest bass channel about 7½in. long by ⅝in. deep; 61st, 4½in. by 7-16in. Then put on a set of 8ft. unvoiced and treble half-set of 16ft. More than one reed on each channel is condemned, though for that matter I have had chords of three notes speaking on one channel at same time. There would be two on treble only. If you have room, mount the sub-bass oct. at extreme back, with separate pallets actuated by lever attachment shown on page 120, No. 577, Fig. 10. Get longer plungers, and if bellows power and space permit, put on super oct. coupler; then you will possess an organ that would please most people. I endorse the grateful sentiments expressed towards past writers in "ours," and think great credit due to its editor for the excellent manner in which the paper is conducted. England can only keep pace with the mechanical progress of other nations by the spread of such knowledge as fills "our" pages, and in which "ours" is not equalled by any periodical I ever saw. I sent information and cuttings from "ours" to a friend, by means of which he made two or three harmoniums. This set him off. He became a subscriber, and is now working in a large organ factory, in his element, and doing well.—D.



[46316.]—**Continuous Brakes on the L. and S.W.R.**—I am informed that the L. and S.W.R. have adopted Gresham's modified form of Smith's automatic vacuum brake. The other handle, which "Brake-Block" noticed near the regulator, was for the continuous brake, either for admitting air or for the ejector. The engine-wheels are fitted with a steam brake for the same reason that the M.R. and G.W.R. are.—Centaur.

[46336.]—**Telephone Circuits and Call.**—After G. Tolman's reply on p. 67, it is almost needless for me to write more; but as I have promised, and thinking if "Meme" has no microphone arrangement, the extra connections might confuse, I append the following figure. When the button R is pressed, the spring H makes contact with support C. A current then flows from battery to C through spring H by means of a wire to B, thence through K to the line. Through the line it enters the other end through K, B, H to D; from D through coil F to terminal T, through the keep and frame G to earth, ringing the bell N as it does so. On taking the telephones off the hooks R at both ends, the currents produced by speaking into them are sent through A to K, and then to line entering K at the other end through A to the telephone there, and from end 2 of bobbin to earth or return wire. These connections can be made out of any old pieces of brass, screws, &c., and fitted up in a box. So long as the contacts are clean and firm, it will work as well as if better made. *K*. Automatic switch arrangement, brass hook pivoted so that a spring fastened to it and point P would keep it down firm on A if telephone M were taken off. A connected with one end of telephone bobbin. B, brass post so placed that K presses firm against it when M is on the hook. H, brass spring normally pressing firm upon D, and capable of being pushed hard against C by means of ebony button R. It is connected by a wire to B. C, brass post connected with positive pole of battery. D, brass post connected to one end of coil of bell movement, F. 2. One end of telephone bobbin connected to earth Z or return wire.—F. C.



[46344.]—**Locomotive Matters.**—In reading the insertion of my reply to this query in the number for March the 31st, I find there has been made a mistake in the numbering of the engines. That with a dome ought to have been marked No. 2, 1877, as will appear from the context. I seize this opportunity to add that this latter engine is fitted with Thieffry's steam jets for the purpose of smoke-prevention. All engines on the P.L.M. line are fitted with this apparatus.—E. Gobert, B.Sc.

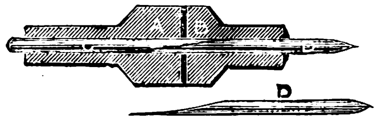
[46384.]—**Balance-Springs.**—"To Guyot."—Years ago, watch-jobbers used to buy hairspring on reels, like reels of cotton, and used to make their own hairsprings. I remember seeing a tool some time ago, in an old watchmaker's shop, by which these said hairsprings were wound. It was very simple, and, as near as I can remember, was like sketch inclosed. A and B are two round pieces of brass, with a hole in the centre; C and D are two pieces of steel wire, like two wedges; C is soldered into A, but B and D are loose. Directions: Put D partly into A; put one end of the hairspring between the wedges, close to the face of A; now push wedge D in tight; now put together as shown, put B into vice; now turn A, which will turn C, which will turn D, which, together, will wind up hairspring, which is being held out somewhat tight with a pair of pliers.—A Fellow Workman.



[46410.]—**Velocity of Discharge from Pipe.**—Divide the product of 57, and the height of the head of water in inches above the orifice by the length of the pipe, added to 57; extract the square root of the quotient, which root, multiplied by 23⅓ and the area of the orifice delivering the water in inches, will give the cubical inches discharged in one second. Then the fall 500in. × 57 = 28,500in. in one mile 63,360 + 57 = 63417 − ·449 √ = ·212 × 23⅓. = 4·946, area of 2in.-pipe, 3·1416 × 4·946 = 15·54in. discharged in one second, area of a 3in. pipe, 7in. × 4·946 = 34·622 in one second.—W. H. S.

[46426.]—**Blackleading Scorched Iron.**—Scour the old black off with emery-cloth, and give two or three coats Berlin black, well thinned with turpentine—say half and half.—Frank Smith.

[46436.]—**Chemical Balance.**—Becker's balances will answer his wants. They are admirable, and the price of one to carry 50grm., and turn with 1mgrm. is, I think, 35s.—F. C. S.

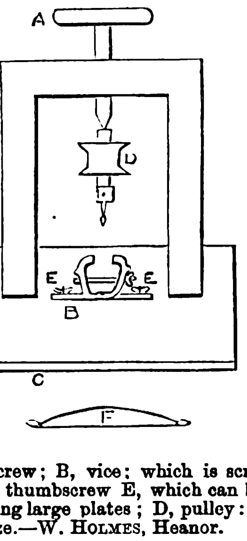
[46436.]—**Chemical Balance.**—In my reply to this, page 88, there is a printer's error, similar to one which, I thought, had occurred in the original query—viz., the alteration of the word "grammes" into "grains." In the seventh line, read "50 grammes" instead of "50 grains."—Arthur E. Morris.

[46441.]—**Vacuum Brakes.**—The brake used on the Bristol and Derby section of the Midland Railway is the Sanders and Clayton vacuum automatic brake. The vacuum is created by a large Gresham ejector on the right-hand side of smokebox; it is maintained by a small ejector under the foot-plate, and destroyed by a patent combined steam and air valve in right-hand corner of cab. A description of the Clayton brake will be found in Nos. 828 and 831 of this journal, and of the Midland steam brake for engines in No. 835. I have not heard of any work yet published on continuous brakes; but Crosby Lockwood and Co. have announced a book by Mr. Reynolds. A great deal of information may be found in the back numbers of this journal on the subject.—Centaur.

[46450.]—**Separating Fat from Mineral Oil.**—"Chandler" must take a fine mesh sieve, say a 40's, and pour the mixture through. This will leave the fat on the sieve. Then make a filtering bag of brown calico, the shape of a pillowcase; pass the oil through; it will then be clear of any particles of fat. To make the fat of any use I should want to know whether it was English melted tallow or rough fat. If "Chandler" will give me these particulars, I think I can help him.—Fellow-Workman.

[46456.]—**To Mr. J. Charles King, or any Wheelwright.**—In the first place, measure the old hub and get the exact size of it. And if there are 12 spokes in the old wheel, make a new hub 1½in. larger in circumference than the old one, and if 14 spokes, make it 1¾in. larger than the old one. (That is allowing ⅛in. to each spoke.) After you have got the new hub turned, set it out for your spokes, and number each mortice, also each spoke; after you have that done, measure No. 1 spoke at the tang, and mortise No. 1 hole in the hub, so as the tang of the spoke will fit tightly. When you have them all mortised, take your saw and saw the hub through the centre of each mortise; after your hub is to pieces, put them all together and fasten a strap round the centre of the hub and measure it; for the front and back hoops, make them out of ¼in. or 5-16in. iron, and 2¼in. wide; bevel the back edges down to ⅛in. thick, and make them to fit very tight. Then take each part of the hub and drive it down between the spokes, according to the numbers. (I have found it a good thing to give each spoke-tang a coat of red-lead before putting them together.) After you have got your hub in its proper place, make your hoops red-hot and put both on at the same time, if possible. As soon as you have got them in their place, cool as quickly as possible, and you will find the joints fit quite close. Dress off and give it a coat or two of paint, and you will find it last for years.—S. T. M. C. Cutler, King's Dragoon Guards, Cavalry Depot, Canterbury.

[46459.]—**Drilling-Machines.**—I think the drawing will be suitable for "Learner." A is the feeding-screw; B, vice; which is screwed on the bed C, by thumbscrew E, which can be taken off when drilling large plates; D, pulley: F, bow; ⅛th natural size.—W. Holmes, Heanor.



[46459.]—**Drilling Machines.**—To drill for pivots you must get a turn bench and screw ferrule, if any real good is to be done. To put a new pivot, see sketch. A, screw-centre, B, drill-centre—this has a handle on end for clocks only; C, pinion to be drilled; D, drill bow. There are several ways of finding centre. Perhaps it will be best for you to use a tool made of a piece of steel about the size of a slate-pencil, with a three-sided point, like Fig. 2. Hold pinion vertically in left hand, and with thumb, first and second fingers of right hand, rotate the tool on centre till a dot is made just large enough to receive point of drill. In fitting new pivot make it perfectly straight, and let it go nearly to bottom of hole in pinion before driving home. If it happens pivot and pinion are out of true, file the side of pivot at end, and so get pinion true afterwards; turn pivot true with graver. After all is true, a centre like Fig. 3 is now put in turns in place of the drill; on this the pivot rests in a shallow cut, the same as a pin rests in a cut on filing-block, and then has all marks took out left from graver with a fine file—a slightly worn file is best; after this a smooth old file, and, lastly, the burnisher. Watch-pivots are put in by the same method. The other part of this query is not in my business.—Skip.

FIG. 1.

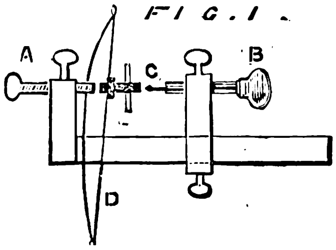


FIG. 3.

FIG. 2.

[46459.]—**Drilling-Machines.**—The article mentioned in this query can hardly be called a machine, being nothing more than a drill-stock in a holder. They are nothing new. I have one with some claim to antiquity, and having three speeds instead of a single ferrule; but so far from finding it useful, I never use it at all, the position of the hand being inconvenient and cramped. No drilling-machine is wanted for watch pivot-holes. You want to be able to "feel" your drill at its work; and even for holes in clock-plates nothing of the sort is required, because in the majority of cases only one hole of a size is wanted, and that not very deep. "A Learner" will find that three ordinary stocks and one archimedean for the larger holes, and about four drill-bows, will prove to be the best drilling apparatus that he can use for the purposes named in his query. Only wedding and similar rings can be made smaller without cutting them, and this is done with a tool in the form of a thick metal casting, circular in shape, and pierced with a number of taper holes. The ring being annealed, and forced into these holes by means of the stakes (which fit each hole), being placed on the ring and struck smartly with a hammer; but if the ring is to be made much smaller, it must be cut. The gold paint I now nothing about; it savours of tinkering.—F. C. Putley.

[46463.]—**White-Lead.**—White-lead is frequently adulterated with chalk. If, on the addition of a small quantity of sulphuric acid to some of the white-lead you perceive effervescence, you may be sure it contains something which ought to be absent.—Hugh Tunnadine.

[46463.]—**White-Lead.**—Any wholesale house would supply pure white-lead. But as you say it is for dwelling-houses, pure white-lead, if for outside work, is apt to scale off in hard flakes after a year's exposure; even for inside use also, unless the ground colour in which it is laid is properly prepared, the same as is done by carriage-painters. This subject will be treated fully at the conclusion of "Cart and Wheel-Making." But with all my experience of pigments and colour-mixing, for which I have received a certificate and prize from the Coachmakers' Company, London, I would, if I had house-painting to do, write to any good firm and say for what sort of work the white-lead was required; for inside, pure; for outside, as fencing and garden-lights, or for walls, with such suitable admixtures as would best serve the purpose required. You would pay only such a price for suitable paint as would prove an economy and satisfaction in the end.—J. Charles King.

[46465.]—**Midland Carriages.**—The longest bogie carriage measures 60ft. from end to end. Those mysterious letters, "M.S.J.S.," simply mean

"Midland Scottish Joint Stock."—W. H. Richmond, Jun.

[46473].—**Pressure of Water.**—In answer to "W. H. B., Bradford," the way to find the pressure is as follows;—

Let D = 8ft. = depth.
W = 12 = width.
A = 4ft. = average depth.
C = 62·5 = weight of a cubic foot of water.
X = pressure.
DWAC = $\frac{1}{3}$

38·4	12
62·5	8
——	—
1920	96 area.
768	4
2304	——
——	3·84
240·000	——

Answer...... 24000lbs.

Then, in the second place, you would take the 2ft. as the height, and 1ft. the average height, and proceed the same way.—T. Sherwood, jun., New Tunstall.

[46481.]—**Boiler-Pump.**—The quantity of water your pump will inject into your boilers is as follows:—You will have to find the area of your ram in inches, then multiply by the length of stroke in inches, which will give the capacity of the pump-barrel in cubic inches. If you wish to have the weight of water, multiply the number of cubic inches by ·03612lb., which will be the total weight it will inject into the boiler. To find the area of your ram you will have to square the diameter and multiply by ·7854 (which is a constant number for finding the area of diameters).—E. Hardcastle, Bradford.

[46481.]—**Boiler-Pump.**—To "Sunlight."—Find the length of stroke and diam. of ram, and multiply that by the number of revolutions the engine, and therefore the eccentric, makes per minute. This will be the volume in cubic inches that the pump can deliver per minute. You can then turn that into gallons by dividing the number of cubic inches of water by 277·274. Had you stated the size and stroke of ram, and the revolutions of engine per minute, either myself or others could have told you exactly what the theoretical delivery would be. But from the theoretical quantity there must be a deduction made, as, except the pump runs very slowly, the barrel does not entirely fill; that is to say, that on the ram making the outstroke, the water does not rush in quickly enough to quite fill it, so that the full capacity of the stroke is but rarely delivered.—Sunlight.

[46487.]—**Chemical.**—If the material which is suspected to contain salt, be steeped in a little distilled water, the salt held by the fibres becomes dissolved. By taking a small portion of this in a glass and adding thereto a little silver nitrate a white, curdy ppt. will ensue. On adding ammonia it will dissolve. This reaction will not take place in ordinary water.—W. H. Binns.

[46489.]—**Bicycle-Making.**—One would suppose, from "Sunlight's" reply to this query, that the pins add greatly to the strength of the joint. This is not the case, for, as ordinarily done, the pins do not contribute to the strength in the slightest degree. They are used simply to keep the parts in position during the process of brazing, for if the peg, or pegs (which need not exceed $\frac{1}{8}$in. diameter), were absent, the necks, hollow forks, &c., would be almost sure to shift while being brazed, and consequently, when finished, would not be in their true position. Any other information if required.—Wm. Granger.

[46489.]—**Bicycle-Making.**—To braze bicycle forks in: first take hollow forks and clean out inside of those intended to be brazed; then take the head and shoulder at about 2in. from the end; put some spelter or brass wire, 18 or 20 guage, and a little borax in; drive into place and bore a $\frac{1}{4}$ hole into fork and through shouldered end of head, then put in a tight pin or rivet over, so as not to show when filed off; then clean outside for $\frac{1}{2}$in. at each side of joint and wrap three or four times round fork, brass wire somewhere about given sizes, and slightly damp joint; then sprinkle a little more borax on outside, and get hot. Be careful not to get tube too hot before the head is hot enough, or else the job is spoiled. Then let it cool, and clean.—Rex.

[46489.]—**Bicycle-Making.**—You must make the wheels first, as they are your guide in forming the framework. If this is a first trial, I should advise making the small wheel first, as it is less difficult, and it would give you a little experience before commencing the large one. The braze alone would hold, but the rivets are necessary to keep the work in place in the fire; they can be made not to show with a little care: countersink the holes and rivet down heads. When in fire be careful not to burn the tube, as it will spoil in no time: I always put a little brass outside, and when that runs I know it is melted inside. I suppose you understand the usual method of brazing? The head should be first brazed to forks, being careful to get them in the same plane as head; then fit in fork ends, put in bearings, and try the wheel in position. If the rim is nearer one side than the other, the fork the near side is too long. This must be filed; but a little does it, as an error here is multiplied at rim. It is much easier to "set" the wheel here than at join to head, and this is why it should be first brazed to head. If there is too much room between rim and head (with tire on), both forks must be shortened; but I should allow nearly an inch, as if too close the dirt collects and falls into bearings, causing them to wear very fast. When the wheel hangs properly the ends may be brazed in. A 3-16in. hole must be drilled in upper part of fork on inside, to put borax and brass in at. Brazing neck and back fork to back bone, or more correctly beam, requires some judgment. The front wheel and forks should be put to gather the neck in its place in head. The beam, when in position, should cover the rim all the way down, as if more on one side than the other the small wheel will not follow the large one, but run in another line at side, and thereby increase the trouble of steering and make more pedal work. When the beam is correctly placed, make a scratch on it and neck to correspond; rivet and braze as before. The small wheel should now be hung in back forks; and if rim should be too near one side, this can be altered by slightly increasing the curve of the near fork or straightening the far side. When right, the forks, with wheel in, should be put in, and so arranged that the small wheel exactly follows the large one, and is quite upright with it. Make a scratch, rivet and braze up. If I can give you any other assistance I shall be happy to do so. Will our kind editor allow me to make a remark in passing? It is really surprising how many readers are interested in queries that, at first sight, appear to be only of limited concern. More than a dozen, and if I counted I dare say score, times I have been on the point of asking something, and the identical question has appeared, although I had been deterred, fearing it was only of personal interest.—Ixion.

[46496]—**Sewers.**—I have sent my copy of the number referred to to be bound, so cannot refer to the original query. The "hydraulic mean depth" of a sewer or other water channel is the sectional area of the stream of water in square feet, divided by the length of the contour or wetted perimeter of the conduit in feet. Thus, if the sewer is of rectangular section, and 12in. wide by 24in. deep, the water flowing through it filling it half-full, the wetted perimeter = 3ft., the area of stream = one square foot, and the hydraulic mean depth is $\frac{1}{3}$ft., or ·333. If the sewer is full, the wetted perimeter is 6ft., the area being two square feet, and the hydraulic mean depth becomes 2-6th, or ·333ft. as before.—Glatton.

[46497.]—**Fortified English Cities.**—I very strongly think that "Antiquary" is mistaken in supposing that the affix "gate" to sundry names of streets in Leicester has anything to do with gateways. Humberstone-gate, not "Humber-gate," and Belgrave-gate, are the gates or ways or roads leading to the somewhat distant villages of those names. Sanvey-gate is the Sancta Via of the Romans, leading to the big church; and Gallowtree-gate, pronounced as if spelt Gaultry, is the road leading up to the gallows-tree, which, I believe, used to stand near the corner of what is now the racecourse. Brig-gate, in Leeds, is the way leading to the bridge. The Appendix to Imperial Dictionary gives "Gate, a road; a way; a street." The German gasse is a street. I don't think there are any signs of walls at Leicester; but the name Leicester is, I believe, derived from its being the castra, or camp, on the Leir, now called Loar river; and camps, I fancy, were not usually walled places.—J. K. P.

[46497.]—**Fortified English Cities.**—As a general rule, I think "Antiquary" may take it that all the English cities were walled, and probably most boroughs protected with earthworks as occasion required. I doubt whether there is any list of walled English towns. From the nature of the work in the "Holy Bones" at Leicester, I think there can be little doubt but it was walled by the Romans, as was Lincoln. The remains of the walls at Chichester and York are interesting. No one need be reminded of the famous walls of Chester, perhaps the most perfect example remaining in Europe. Goodwin, in the "English Archæologists' Handbook," says — "Canterbury, Nottingham, and York are mentioned in Domesday-book as having been surrounded by a fosse; Oxford, Hereford, Leicester, Stafford, Chester, Lincoln, and Colchester as walled towns and burghs." Nottingham, was, however, then walled with a fortification built by Edward the Saxon, and portions remain. The word "gate," for street, is no indication of fortifications when used in Midland and Northern towns. It there means "way," as in the common saying, "Gang thy own gate"—*i.e.*, go your own way.—Iota Pi.

[46499.]—**Lathe.**—My fly-wheel is carefully fitted on end of crank-shaft, and a set-screw passes through boss at right angless to shaft, nipping the latter tightly, so as to prevent wheel slipping. Steel centres are generally used; but, if well made, gun-metal bearings would be better.—Glatton.

[46501.]—**Length of Exposure.**—(1) This is a very difficult question to answer satisfactorily. As duration of exposure depends on quality of light as well as class of subject and rapidity of sensitive plate, and as the former fluctuates with every change of wind and weather, nothing definite can be stated. The required knowledge can only be obtained from much experience. (2) The stops of lenses by the best makers are supposed to be calculated and marked so that those with a whole number shall need an exposure twice as long as the one immediately preceding, those with a +, half as much again as the next size larger aperture; but this arrangement is not always reliable—in fact, is seldom correct. (3) This having been up to the present in a most unsatisfactory state, has rendered it incapable of treatment in the instruction books; a committee of the Photo Society has, however, just been formed to endeavour to reduce the difficulty to a practical method.—Baboon.

[46501.]—**Length of Exposure.**—Supposing the full aperture of lens is 1in., and the ascertained exposure 1sec., then, all the conditions being the same, a $\frac{1}{2}$in. stop would require approximately 4secs., and a $\frac{1}{4}$in. stop 16secs.; other sizes, a proportionate increase or decrease. It cannot, however, be too strongly impressed upon beginners that the art of giving correct exposures, under all the varying conditions met with in practice, can only be acquired by practical experience, and although it would no doubt be rather expensive to make experiments with 8 by 5 plates, surely "Beginner" could afford to make a few trials with quarter-plates. By the way, I hope no "beginner" will be misled by the recommendation as to exposure on p. 77, for unless an exceptionally small stop be used, it must be a very slow gelatine-plate that would stand an exposure of 5secs. under the conditions named. From 1 to 2secs. ought to be ample, even with the lens stopped down to F. 20 or 30.—W. Robinson, jun.

[46501.]—**Length of Exposure.**—To determine the length of time that a plate should be exposed is a simple mathematical operation. We know that the light which reaches the plate through the stops is expressed by the following proportion:—

$$\text{As} \left(\frac{\text{the focal length of lens}}{\text{diameter aperture of stop (1)}}\right)^2 \text{ is to } \left(\frac{\text{the focal length of lens}}{\text{diameter aperture of stop (2)}}\right)^2 \text{ so is}$$

the amount of light which passes through stop (1) to the amount required, which passes through stop (2). To reduce to practice, take the focal length of your combination, which we will suppose is $7\frac{1}{2}$in., and divide this by the diameter of the aperture of the stops, which we will suppose are $\frac{3}{4}$in., $\frac{1}{2}$in., $\frac{3}{8}$in., and $\frac{1}{4}$in. respectively; this will give the focal length of lens, divided by the numbers 10, 15, 20, and 30, or, as it is generally written:

$$\frac{f}{10}, \quad \frac{f}{15}, \quad \frac{f}{20}, \quad \frac{f}{30}.$$

Square all these numbers, which will give 100, 225, 400, 900. Now suppose the stop $\frac{f}{10}$ requires one second's exposure, the next stop $\frac{f}{15}$ will require 100 : 225 : : 1 : x, or $2\frac{1}{4}$ seconds, and so on through all the stops.—Stanley T. Hawkins.

[46511.]—**Stains in Dry Plates.**—These can easily be removed by a wash of acidified water; HCl, say, 1dr., water 2oz., is as good as any. Tin dishes are quite safe; for quarter-plates I not unfrequently use an old sardine tin; it is just the thing.—W. Robinson, jun.

[46511.]—**Stains in Dry Plates.**—(1) By the addition of citric acid to the developer in the proportions of 1gr. to every 10 of pyro., or by dissolving a few grains of sulphite of soda in each ounce of the strong developing solution. (2) If you confine yourself to alkaline pyro. development, you may use tin dishes.—Baboon.

[46515.]—**Cast Malleable or Annealed Cast-Iron Castings.**—Put about 14lb. of malleable iron borings into 1cwt. of melted metal, put the borings into the ladle, and then catch your metal at the furnace; put in a little extra coke into the cupola, so that your metal will be hot. Hematite pig is tougher than common pig. Could you not cast a wire in each casting?—a piece of common cage-wire.—Cast Iron.

[46519.]—**Kirk's Double-Expansion Compound Engine.**—The expansion in two cylinders is not, in practice, always more economical than in one. The reasons leading to this form of engine are chiefly these:—(1) It is always desirable to maintain cylinder at one uniform temperature; and with high rates of expansion the temperature of steam varies so much between the beginning and end of expansion that it is impossible to obtain anything like even temperature throughout this expansion. It the expansion is spread over two strokes instead of one, the steam will be cooled to the same extent; but the extremes of temperature in each cylinder will obviously be reduced. (2) By setting cranks at right angles, and properly proportioning areas of pistons, the strains are more evenly distributed during one revolution of crankshaft than they can be with one cylinder.—GLATTON.

[46529.]—**Varnish for Violin.**—"War" asks a curious question, "Is there any dependence?" &c. Now, I would opine that, as in all other trades, there may be found even an honest fiddle factor; but I have not yet established to my own satisfaction that there be such a homo as an honest horse dealer. I am satisfied with French polish for violins.—J. J. A., Liverpool.

[46530.]—**Rotary Water Motor.**—You cannot, I should think, do better than use one of Bailey's, as advertised in these pages.—J. J. A., Liverpool.

[46536.]—**Shaft.**—Presumably you intend to use pulleys, so the belt will not work if they are placed where the shafts cross each other. Had you given the size of your pulleys, you might have had an exact answer. However, you may find their position by knowing that a plumb-line held against the centre of the rim of the upper one must just touch the centre of the rim of the lower. These are points of delivery of the belt.—W. J.

[46539.]—**Water Power and Electric Light.**—J. Hezmalhalch appeals to me with regard to the stream of 2½ gallons. I saw his query when it previously appeared, but could not give him a very hopeful answer, so left it for someone else. His stream having a fall of 42ft., and weight of water being 2½ gallons at 10lb. each = 25lb., gives a total energy of 1,050ft.-lb. per minute. A water-motor will not utilise more than 50 per cent., or, say, 500ft.-lb. per minute. (This is without any allowance for loss of heat by friction in 1½in. pipe.) As there are considered to be 33,000ft.-lb. per minute to one horse-power, this will be equal to 1-66 of a horse-power, and I do not know where J. H. is to get a dynamo that will work with so little power. I am now making as small a machine as I can, and I calculate a man will be just able to turn it (which is equal to about 1-10 horse-power, or 3,300ft.-lb.), and that it will work one incandescent lamp. Perhaps, by storing the water and running it away rapidly, more power might be obtained for a short time; but under the most favourable circumstances, it would not do more than light one incandescent lamp for two to three hours each day. Storage batteries are out of the question, because there is no electricity to store. A Swan lamp is said to take 1-10th horse-power, but I have generally found that seven or eight lamps per horse-power is nearer the mark.—R. P.

[46542.]—**Broken Steam-Gauge.**—I had one of "Bourdon's Patent," with the tube split. I had it soldered by a tinsmith; it then did its work as well as before.—CAST IRON.

[46543.]—**Executors and Legatees.**—This is a case of a vested legacy, the payment of which was deferred until the legatee came of age. She is now over age, so that condition is fulfilled. The only other question was whether the executor had money enough to pay the legacy with after providing for the debts. By the writing he gave, this difficulty is got over, because he has admitted having assets, and assented to the legacy. The legatee should, therefore, now bring an action against the executor for payment of the legacy, either in the High Court, or, if the estate be below £500, then in the proper County Court. If the legatee consults a solicitor she will find she is not at all helpless; but, presuming the facts are as stated, will soon get her money, which, if the uncle dies badly off, she may lose altogether.—FRED. WETHERFIELD, solicitor, 2, Gresham-buildings, Guildhall.

[46547.]—**Jewellery Repairing.**—To get out rivets from brooch-joints, it is as well to know that jewellers as a rule put them in always the same way; that is, looking at the back of the brooch with the joint held at the top, it is "pinned up" by pushing a tightly-fitting wire through (slightly tapered) from right to left. It is not riveted, except in the case of a very old and worn joint. You can make a pusher out of an old bradawl, or any similar tool, ground down to the size of the rivet, but in case the pin is riveted in, it must be punched out. For this purpose nothing is better than a thick needle, with the ends nipped off. Holes are enlarged with a "joint broach," to be obtained of any jeweller's tool dealer. To file down the pin, put it in a pin-vice, file a notch in the edge of your bench, or the piece of hard wood you use to file on, lay the pin in the notch and twirl the handle of vice round while you file the pin. With a little practice you will do that all right. Then put a piece of wire in the pin-vice and file that down to the required size, and pin up the joint-tongue from right to left, as above described. If the coin is to make a brooch for home use, you can soft solder on the joint and catch, but it would not be either strong or workmanlike. If you want to do several for sale, you must acquire the art of hard silver soldering, which will require a good deal of practice, but will well repay you if you want to make good work. Soft solder is useful for patching up articles that you don't want to re-gild or re-colour; but no good workman likes to use it, and if once used on an article makes it very difficult to properly repair it at a future time. If you care to go thoroughly into it, ask again, as this reply may be considered quite long enough already, and it would take another reply equally long to explain hard-soldering, and would then take heaps of practice before you were perfect, as the goods have to be made red-hot, and there is a risk to a novice of burning, and perhaps, melting the article.—J. E. A.

[46547.]—**Hard Soldering.**—If "Blue Gown" will refer to some letters of mine on the subject of soldering, the numbers of which were quoted in "Answers to Correspondents" in No. 887 of the "E. M.," he will, I think, glean something useful to him. Joints and catches may be fixed on brooches, of whatever kind they may be, either by soft or hard solder. In the case of coin-jewellery, hard-solder is best. This may be procured in small quantities of any obliging jeweller; sixpennyworth will do twenty jobs. If not so procurable, get a small piece of good silver and melt it up with about twice its weight of good brass wire; then hammer it out thin, and use as required. In melting the solder use borax as a flux. In giving you a little instruction anent your query, I must premise that you have provided yourself with the joint and catch, which should, preferably, be of silver, although if of German metal, it does not matter. Get a piece of pumice-stone, and rub one side flat, taking care that the surface is clean; then fix the joint and catch in their respective positions on the coin, having previously applied a little moist borax to the surfaces in contact, and bind them over with fine iron wire, taking care in so doing that the wire does not touch the parts where the solder is required to flow. Molten solder exhibits this peculiarity—that, in whatever part the greatest heat is applied, it flows to that point, so that if the heat is misapplied, the solder flows anywhere but in the desired place. Having bound the coin with wire on the flat side of the pumice-stone, to prevent it slipping off, apply the little pieces of solder to the joint and catch, and with the gas and blowpipe steadily raise the heat until the solder is seen to flow. Stop blowing at once then, and examine to see if the connection is perfectly made. If not, apply a little more borax and solder, and repeat the operation of heating. The flame, which should not be larger than (what shall I say?) the top of a small wine-glass, should be directed just a little behind the joint or catch, the solder being put the other side, and so be drawn under when it melts. When the parts are properly soldered on, remove all traces of wire, and immerse in the vitriol solution as described in my letter. Allow it to remain therein for an hour or two, when it must be taken out and swilled in clear water. It should come out a pure dead white. If it is desired that this white bloom be preserved, do not brush it in any way—simply wipe dry, or dry in hot sawdust. If you require it to be bright, brush it with rouge or any polishing material, and rub up with chamois-leather. To remove rivets from brooch-joints, the burr, or rivet-head should be filed off, and the pin pushed out either with a steel point or be removed with the nippers by putting the point of one jaw on the broken pin, and the other on the end of the rivet, and so force it a little way out, and then take hold of the protruding end with both jaws and pull out. Another way is to put an old watch-key in the vice, place the joint over it—i.e., resting upon it—and drive the rivet out with hammer and pin-push. The holes of brooch-joints and pins may readily be opened with suitable "broaches," which are long, slender tools with four or five cutting edges upon them, and to be bought for about threepence at any trade-tool shop. They are sometimes called "rimers." To produce a good and tapered point to a pin, you will need a pin-vice and filing-block, together with rough and fine files, and a burnisher. Take the pin-vice in the left hand, having previously fixed the pin firmly in the centre of the jaws, and with the file in the right, and a shallow rut cut in the filing-block, proceed to file and twirl the pin-vice with a rapid, steady motion, always observing to keep the pin going in the opposite way to the thrust of the file. Bear in mind what you desire to obtain, and work to that end, always bearing on the file more to the side of the point. When roughly shaped, finish off with a fine file, or Ayr stone, and burnish. In cutting the pin-joint to fit, be sure to make it square with the brooch-joint. Let the hole in the pin-joint be a shade larger than the others; then, if the rivet is properly filed up, it may be forced in sufficiently tight to hold secure with little or no riveting over. The pin-point should protrude about a ¼in. beyond the catch. If you require further information, seek and ye shall find.—ALFOJOE.

[46548.]—**Pulleys.**—Grooved pulleys are generally used for small powers, as giving greater grip than such belts as could conveniently be used. The practical objections to them for machinery is that they cannot be shifted from a fast to a loose rigger when it is desired to stop the machine without stopping the power. V-grooves are generally thought to give more hold than round ones; but "D. H. G.," in his valuable articles on overhead gear, laid great stress on round grooves with belts to fit them accurately as being less liable to slip. The usual V-groove has usually a vacant space at the bottom, so as to put the grip on the sides of the belt, which does not seem to deteriorate it, but rather to improve it by the compression. A round groove does not act well, unless the band fits it very exactly.—TREADLE.

[46550.]—**Instantaneous Photography.**—If the plates named were really as sensitive as they were said to be, there should have been no difficulty in obtaining good negatives in far less time than you could uncap and re-cap the lens, supposing, of course, that the conditions were favourable and you did not use too small a stop. Are you sure they were not very much over-exposed? Mr. Muybridge's horses were taken, if I remember rightly, against a white background, which would enable an outline of the horse (which was all that was required) to be taken with a very brief exposure indeed.—W. ROBINSON, jun.

[46550.]—**Instantaneous Photography.**—Mr. Muybridge's photographs are mere silhouettes. They were taken on wet plates in an incredibly short space of time, and while passing in front of a brilliantly-lighted white background, the short exposure being sufficient to impress the latter without giving any details in the animals. The reply to your second query resolves itself into a question of light. If this be of the powerfully actinic kind as that which proceeds from a sky flecked with clouds after a sou'-wester, in the months of April or May, the plates you mention would give a fully-exposed sea-view in the time stated, and perhaps a well-lighted landscape likewise. Plates may be prepared exquisitely sensitive, but still the main consideration is the quality of the light; and for this reason, successful rapid pictures can only be obtained on a very few days in the year. In developing, use as little restrainer and as much ammmonia as possible, consistent with the non-production of fog or flatness.—BABOON.

[46551.]—**Unseasoned Wood in Furniture.**—A sure test, if the furniture has been turned out of hand for some little time, is to rub the fingers over the joints, and, if any difference of level is perceptible, the wood has been worked up before being thoroughly seasoned.—J. J. A., Liverpool.

[46553.]—**Riveting Copper Boiler.**—The method I employ is to rivet in the front end, and then to have the shell, say, 1in. longer than requisite for steaming purposes. Place the end of the boiler, with the flange for riveting outside, and rivet up; cut an aperture for the chimney and rivet it on this inch length; then rivet in another end for smoke-box, only putting two rivets in this, as you may require to take it out some time or another, if you allow the boiler to run short of water, and so spring a leak. Then with a Bunsen burner heat, and sweat solder into all the joints, put a flue through the shell and apply the lamp, so that the flame begins at the end where the chimney is above, travel to fore-end, up into, and through the flue, and so into the smoke-box and up the chimney.—J. J. A., Liverpool.

[46554.]—**Plumbing.**—"Oilman" cannot do better than employ his friend the plumber to line him a 3ft. square cistern by 3ft. deep, say 5 or 6lb. lead, have a bricked-up hole at the required depth to receive cistern, take care that the brickwork is only just large enough to receive the cistern, unless you have 1½in. sides. Another way: build your brickwork, then all round bottom angles, and also up two of the upright angles, fix some slating springing for soldering against, and line it with lead as you would were it a lead cistern; of course, you must not attempt to do this yourself, because if a leakage should be at the joints, you would lose a lot of oil before you knew anything about it, therefore such a job requires to be done well. Put in a wood bottom under the bottom lead. In this last plan your cistern may be made to any shape, round preferred; the only thing to keep in view is to fix woodwork, say, ⅜in. to ½in. thick, for soldering against and a good wood bottom. I should fit the engine with ⅜in. lead pipe.—P. J. DAVIES.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

* Since our last "Carstairs" has replied to 34041, 34042, 35398; F. C. Putley, 45765, 45766; "D. W. C.," 45990.

QUERIES.

[46556.]—**Skin - Disease.**—To Dr. Edmunds.—I should feel very grateful for advice on the following case:—Some four years ago an eruption broke out on my face, and ever since it has been spreading and getting gradually worse. It has taken root in my whiskers, and looks like a little scab around each hair. When I pull a hair out, the root is either quite black or charged with matter, and tinged with blood. Some two years ago I met a person who had a slight attack of the same sort, and he got rid of it by plucking out the hairs by their roots. I tried that remedy, but with no success. My doctor does not seem to understand it, and has given me the following remedies in turn:—1, Sulphuret of potash; 2, iodoform; 3, crysophanic acid; 4, a solution of chlorate of potash in very dilute hydrochloric acid; and lastly, a lotion to be sparingly applied, and strongly charged with arsenic. I have been trying these remedies for over two years, and am not one jot the better. I may also state that I have tried a well-advertised blood-mixture with no success.—Sufferer.

[46557.]—**Spun Wire.**—Will any of our readers kindly explain the method adopted in covering the bass wires of a pianoforte with copper wire, and describe the machine employed for this purpose? Could not our esteemed friend, Mr. W. H. Davies, furnish the desired information?—G. Fryer.

[46558.]—**Oil for Canvas Belting.**—Can any reader of "ours" tell me the kind of oil or mixture with which the new canvas machinery belting is saturated? The belting is made of four pieces of canvas sewn together, and appears to be saturated with a kind of quick-drying oil, which holds the canvas together, and makes it flexible.—Com.

[46559.]—**Sharpening Carpenter's Saws.**—General directions for the above would be very acceptable. More especially as to using proper-sized file, and as to the angle the teeth should be reset.—Tiro Tironum.

[46560.]—**Tuning Piano.**—To Mr. Davies.—My piano is nearly two whole tones below concert pitch. It is quite new, but has been terribly neglected for the past winter—left in a damp room, &c. I got it tuned a few days since, but the tuner would not raise it; he said it would be down the following day. Can I get it up by degrees myself? No chance of a tuner for six months. I have tuned an old piano myself, but I don't like meddling with this without advice. Is there any contrivance made by which I could tune the centre octave (C to C), sharps and flats? The chief difficulty lies in that, as it is easy enough to get the octaves when that is correct. The action is "check," and squeaks from damp also. Is blacklead any use? If so, please say how to apply it.—R. H.

[46561.]—**Water Supply.**—A. and B. buy houses adjoining. The water supply is intermittent; the pipe from main comes through premises belonging to A., and supplies a cistern on same premises, from which B.'s pipes are run. Now this cistern is continually a nuisance to A.—either leaking or running over. Can A. compel B. to have separate supply from main? If so, how can he best go about it? By doing so, a smaller cistern would answer A.'s purpose, and prevent occasional unpleasantness between the two parties.—Frank Smith.

[46562.]—**Drying Gelatine Emulsion Plates.**—I have a room, 18ft. by 7ft., flagged with slate flags, lean-to roof, average height, 10ft., open to roof, which I propose to partition across the middle, using the outer room for preparing the plates in, and the other I wish to fit up as a drying-room. I should be obliged for any hints as to the best method of warming and ventilating, so that the temperature (60° or 70° F.) may not vary much during the time the plates are drying. Gas is not available.—J. G.

[46563.]—**Washing Photographs.**—I should be glad to know of an efficient method of washing batches of 70 or 80 photos.—sizes, 12in. by 10in. and 15in. by 12in. There is an unlimited supply of water at high pressure. Do self-acting siphon-troughs answer well?—J. G.

[46564.]—**Organ.**—I have a small three-stopped organ, 4½ octaves; two stops have pipes. The front set of pipes belonging to the other stop is missing. There are no names on the stops. What I want to know is, whether the front set of pipes ought to be wood or metal. If wood, I could make them myself if I had a scale; but if metal, I must buy them.—Hebe.

[46565.]—**Legal.**—To Mr. Wetherfield.—There are two trustees in an estate (A. and B.). One of them (A.) is a lawyer. If A. should invest trust-money without B.'s knowledge, is B. liable in case the money be lost? Or if A. turn bankrupt, and all or part of the trust-money is found to be squandered, is B. then liable to refund it? Is there any useful legal handbook on the duties and liabilities of trustees?—Qui Non Legem Intelligit.

[46566.]—**Deafness.**—Will Dr. Edmunds kindly say what remedies must be used in cases of partial deafness arising from a stoppage of the eustachian tube from colds or similar causes?—Q. V.

[46567.]—**Micrograph.**—I want to make some microscopic portrait transparencies for the microscope, and will thank some friend to tell me how best to manage. I have objectives by our best makers, ranging from 2in. to ⅛in. I want my pictures not larger than a—Pin's Head.

[46568.]—**Revolving Gas Burners.**—Will some correspondent oblige with description of these arrangements? I want to construct something with four or five lights, that will turn in about a circle of 8in. A small plan would be a great help.—Crutch.

[46569.]—**Boiler.**—I have a steam-engine 3in. internal dia. by 4½in. stroke. I want a boiler to supply it with low-pressure steam, never to exceed 10lb. per in. Will "Sunlight," or any other correspondent, inform me what sized boiler I require to drive at 300 revolutions per min., and what would be the probable cost? The engine will not bear a high pressure, but is constructed for high speed. I am aware that low pressure is not economical; but as I intend to use waste fuel, that is of less importance to me than a high first cost would be.—Elephant Bill.

[46570.]—**The Weight of Metal by Measuring It.**—Will "Cast Iron," or some other eminent correspondent, tell me the way to ascertain the weight of a ladle of metal by measuring it? I think a few hints on casting would gratify many subscribers.—Metallurgy.

[46571.]—**Air-pumps.**—Could any reader kindly give a description of the McLeod gauge used for measuring the degree of exhaustion produced by mercurial air-pumps, its dimensions, size of the divisions, method of calibrating and using, &c.?—Plodder.

[46572.]—**Sound in Pipe.**—Will any reader kindly answer the following?—I have had a 1in. pipe fixed to large water-tank, which is heated by steam, to supply bath-rooms with hot water. The pipe runs past several bed-rooms. Now when the steam is turned into the tank (which is always done at 4 a.m.) it makes such a noise in the pipe that it wakes the occupants of the bed-rooms, which is not pleasant at such an early hour. What can be done to stop it? Would a few feet of the iron pipe cut out, and rubber pipe put in, break the sound? If not, what is the remedy? The tank is about 50ft. from the bed-rooms. There is a tap against the tank, but whether open or shut it is just the same. The water is heated to 180° Fahr.—Anxious.

[46573.]—**To Mr. Wetherfield.**—A. dies in 1870, leaving B. (his widow) sole executrix. The property left consists of four cottages and a small piece of building land, value altogether about £600, on which there was, and still is, a mortgage of £200. B. has not proved or administered to the will, but simply received the rents and paid the interest on mortgage as it became due. She wishes the property to be divided equally amongst her three sons. Please say how to proceed—if there will be a fine for not proving will sooner; and if so, how much? The witnesses to A.'s will are living.—West Yorkshire.

[46574.]—**Photo. Bath.**—What is the cause of stains same shape as the marbling on book-leaf edges, only they are white? Books say dirty carriers is the cause; but that's not so in my case. I am particular to have all my apparatus scrupulously clean. Those stains show as soon as iron developer is applied. Will somebody explain cause and cure?—Ouvrier.

[46575.]—**Photo. Lenses.**—To Mr. Lancaster.—I possess a double-combination photo. lens 2¼in. dia., and 6½in. back focus. The former owner was fond of experimenting, and so spoiled the lens in the following manner:—The tube has been cut shorter, and the two back glasses brought nearer together, and the difficulty is, readjusting the combination to proper position. The diameter and focus are precisely as I have stated. Will Mr. Lancaster tell me how to find the proper arrangement without the use of any mathematical formula?—Ouvrier.

[46576.]—**Embossing.**—Will some reader inform me if I can take prints from engraved copper plates and transfer them to bright steel plates, and emboss with acids? Or if there is a better and quicker way than painting on with the brush.—Novice.

[46577.]—**Telegraphy.**—Can any reader kindly inform me how I can obtain an account of Duplex telegraphy as applied to submarine cables? And also of any other methods by which the carrying capacity of a cable is increased?—R. Y.

[46578.]—**Roof Ventilator.**—I am about to build a new house, the ridge of which (on top of slates) will be 30ft. long; and will one of our subscribers oblige by suggesting the best form of ventilator for the roof on the ridge, and whether two will be required for such a length? It is a plain straight roof "hipped off" at ends.—W. Q. R.

[46579.]—**Continuous Brakes.**—Can anyone inform me what brakes are in use on the G.N.R., Midland, and L. and N.W. Scotch expresses, and S.E.R. Continental express?—C. M. T.

[46580.]—**Governors of American Colonies.**—Where could I ascertain the names of the different consecutive governors of the American States while they were still British Colonies, from the first, Lord Delaware, to the last previous to the Declaration of Independence? Also if their portraits are in England and where they may be seen?—Shah Jehan.

[46581.]—**Oxalate Development.**—1. I prepared some time ago (for use in the wet process) a stock of saturated solution of ferrous sulphate to which was added a little cuprous sulphate. Will the presence of the copper salt act injuriously, or altogether prevent this solution being used in dry-plate oxalate development? 2. Can other neutral oxalates—for instance, the sodium and ammonium salts—be employed as well as the potassium oxalate?—W. H. S. W.

[46582.]—**Pressure on Wheels of Railway Carriages.**—Will some of our readers give me some rule to find the pressure on each wheel of our railway carriages? I believe on the Midland, with the automatic Sanders' brake, they get about 1½ ton on each wheel. I can get the lifting power of cylinder, but I cannot calculate the leverage. I can also get the length of the levers. It must be a simple rule.—H. Edwards.

[46583.]—**Small Quantity Battery.**—I am afraid our esteemed contributor, Mr. Lancaster, is ill, as I have not seen any question answered by him the last two weeks. I shall be very thankful if Mr. Tolman or some other kind correspondent will answer as follows:—Can I have a small battery (without liquid) that will fuse a fine wire? I have made a chloride of silver one, but that will not do it. I know a small bichromate would do this, but I want one without the necessity of withdrawing the zinc when not in use, and that would stand being turned upside down, and be permanent (say) for a few days.—Carbon.

[46584.]—**Legal.**—A garden in front of a terrace of houses, and through which lies the approach to said houses, has had no gate hung in the gateway for sixteen years. The owner of the adjoining ground and house says the public have thereby acquired a right of entry into said garden. He therefore claims the right for the occupants of his house, and declares he will not permit gates to be erected now. Is his law good?—Fiat Justitia.

[46585.]—**An Organ Smothered.**—A fine and large organ is placed in an ill-constructed chamber in a non-resonant church. Everybody is disappointed who hears the instrument, as very little of the tone gets beyond the chancel. No alteration in position of organ or in construction of chamber appears to be possible. I have heard that wires extended along a building will aid in the transmission of sound. Will any correspondent who may have had experience of their use advise me, or tell me where I can get information respecting them?—Unhappy Organist.

[46586.]—**A Ruinous Wife.**—How can I restrain a drunken wife from pawning her clothes, &c., or my property? I have been distinctly told in her presence by a police officer that a wife cannot "rob" her husband were she to take the very shirt off his back. How can I restrain her from borrowing money under false pretences?—An Unfortunate Husband.

[46587.]—**Dynamo Machine.**—Will any brother-reader help me to construct one of the above? My present one fails to give any current when the armature is revolved, and so I conclude the wire is not wound properly. What I want to do is to construct an entirely new machine—Siemens' system—to be driven by a half-horse engine. Will any reader give detailed particulars of the winding of the wire, and if it should be covered with guttapercha, as well as the size?—Engineer.

[46588.]—**Telescope Lenses.**—To "Aldebaran."—On p. 608 you say it is of the greatest importance to fit the lenses square to the axis of the tube. Now I have a very excellent three-draw marine glass, but the tubes seem to have got so loose through wear that when it is fully drawn out I can move the one holding the eyepiece quite ¼in. either way, and yet it does not seem to interfere with its definition at all—how do you account for that? I do not put this query to try and prove you are wrong in your statement; but as I intend trying to make a telescope, and as I doubt if I can fix the glasses quite true, I want to know whether the axis being moved out of the centre would spoil the definition more in an astronomical telescope than in any other, and if so, what is the reason of it?—J. L.

[46589.]—**Sack-Marking.**—I shall feel obliged to any of your readers who will be good enough to inform me how to make an indelible ink for marking corn and flour-sacks with, and whether the same should be applied with a stamp, and what kind of stamp, or with a brush and stencil-plate?—H. H.

[46590.]—**Legal.**—To Mr. Wetherfield.—Can a purchaser of ordinary and county court debts recover the same by legal processes in the name of the original creditor without an assignment? Or, having an assignment, can he proceed in the name of the original creditor, the assignment empowering him to do so? Can cases entered for judgment be assigned as well as those not so entered? Which is the most reliable work on County Court practice?—A Subscriber for Thirteen Years.

[46591.]—**Adjustable Plane.**—I want to construct an adjustable plane for concave and convex work, to be made of iron with a steel bottom to bend to the different curves. There is one in the market—an American patent. Should I be infringing if I made one for my own use?—Cyclops.

[46592.]—**Deed of Gift.**—To Mr. Wetherfield.—A father conveys to his sons his house property under deed of gift, he (the father) retaining by agreement a life interest only; after which, can the property be sold or mortgaged by the father, or is such an absolute disposal of all control or power over such property?—Legal.

[46593.]—**Automatic Musical Instruments.**—Would "A. S. L." (19837) kindly say where the "Organette," not "Orguinette," may be seen? I am acquainted with most instruments of the automatic principle, but this is new to me, and I should like to see or hear it. The Organina is on a similar principle, it appears, but it lacks power. I should like to obtain an instrument with more power than the Orguinette. I refer to the small instruments with attachments. Also, can anyone describe the way of the tools by which the sheets are punched or perforated?—More Light.

[46594.]—**Heating Water.**—Would Mr. P. J. Davies or someone kindly give some advice? I have a tank fixed for heating water—it holds 20 gallons. We have steam-pipes for heating purposes, so I fixed a ½in.

pipe in the tank with the end hooked a little, then joined it to the heating pipes. It boils the water very well, but if it is not watched the hot water boils back in the cold cistern and overflows cold cistern; ball cock, &c., soon get out of order. I have an exhaust-pipe the same size as feed-pipe, and there is a lot of steam wasted. Could I in any way carry it back in the main again without danger to the tank? We want to boil the water in half-an hour—our boiler is steamed at 10lb. or 12lb. Any advice to help me out of this trouble will oblige—Jeff.

[46595.]—**Patched Boiler.**—There is a patch bolted on the boiler packed with red and white-lead and canvas. It soon leaks steam. What kind of packing would you recommend? I want to make as good a job as I can with the same bolted plate. It is about 6in. in diameter. What kind of packing would you recommend for steam-pipes generally?—An Amateur.

[46596.]—**Sugar Boiling.**—I would feel obliged if any reader of the "E. M." could kindly inform me the plant necessary for sugar-boiling on a small scale?—J. C. A.

[46597.]—**Gelatine Emulsion.**—Many thanks for the answer to my queries on the above subject. May I trouble W. J. Bashford again as to the following?—After mixing my toning-bath some seven or eight times, a black deposit is formed. The bath is made as follows:—Chloride of gold, 1gr.; acetate of soda, 30; water, 8oz. It is kept in the dark room away from white light. Can Mr. J. Bashford tell me how to stop this deposit from forming? 2. I have made my emulsion and added the acid, and it is less sensitive when dry than when wet (or properly set). It was cooking at a temperature of 93° Fahr. heat for 18 hours, and is but very little more sensitive than some which had not been cooked at all. The emulsion was made from gum. If Mr. J. Bashford can give me a proper formula for making an emulsion free from fogging and frilling, and fairly sensitive twenty times, I shall be extremely obliged to him.—Dark Slide.

[46598.]—**Problem in Plumbing.**—I have a cistern made of tile and cement, with 2ft. 5in. of water, which for certain reasons must not be emptied nor harsh means used against it. The supply pipe to boiler of range is very old, and has been cobbled about much because of leaks, and to stop the supply from cistern. I have tried to plug it with several gentle contrivances, but all to no purpose. Perhaps some of "ours" may put me in the way of doing it in a very quick and easy manner. The pipe projects in cistern, and is about 1½in. from bottom.—G. B.

[46599.]—**Photographic Portrait Lens.**—I have a portrait lens, which I think is defective. When focussing on white paper there are blue and yellow coloured lines round the edges of the image. Would separating the two lenses correct this, and if so, what distance?—Dry Plate.

[46600.]—**Legal.**—Will Mr. Wetherfield kindly answer the following?—A. left C. and D. the interest during their lives of all money in the 3 per cent. to be equally divided. The survivor to receive the interest on the whole, and at her death the stock to be divided in equal parts between her nephews and nieces—share and share alike. Can E. (one of the nieces) leave her share, in case of her death, to her children?—Phares.

[46601.]—**Double Object-Glasses.**—Has the correspondent who asked this question tried the arrangement of lenses recommended, and with what results? As I am trying to make up a telescope cheaply, and cannot afford to buy an achromatic o.g., any information on the subject will be thankfully received. I wish to get the best results with a simple lens o.g., without using a concave eyepiece.—Poor Amateur.

[46602.]—**Pendulum Springs.**—Will "Nicholls" tell me how to determine the size and strength of a pendulum spring for a new watch? I have succeeded in doing the other job that I wrote you about. Thanks for information.—Pivoter.

[46603.]—**Induction Coil Failure.**—Will one of "ours" kindly say what is probably the matter with a coil I have just made? Tube, paper, à la Dyer; core, 9in.×1in., soft No. 17 wire; primary, two layers No. 16, cotton; soaked in paraffin, smoothed, and then wrapped round with a piece of guttapercha 1-16in. thick; over this two folds of letter-copying paper. Secondary, 1½lb. of No. 36, silk; each layer varnished twice with shellac, and then wrapped with two folds of above copying paper also varnished. Condenser, "Dyer." Battery, one quart bichromate. Result: contact-breaker hums like large bee; but secondary spark only just visible. Connecting galvanometer with secondary and battery only, no deflection on making or breaking contact. Connecting it with secondary, and battery with primary: strong deflections; but, as this occurs just the same when the galvanometer is lying disconnected a foot from the coil, I presume it is merely the excited primary does it. On connecting the two ends together a loud rattling accompanies the humming, which gradually subsides when these wires are separated. On turning to back vols., I find many instructions vary considerably. One says: "Use guttapercha tissue for insulating secondary coils." Another: "If you have made use of guttapercha, I see nothing for you but remaking," &c.; so that I am dubious as to where my fault is. I made a regular "Dyer" some time ago, with what a correspondent calls "his clumsy insulation," and got a good ¼in. spark from ½lb. of 39; I therefore want a good 1in. from my present coil.—B. H.

[46604.]—**Incandescent Lamps.**—Can any reader give any definite information as to the behaviour of Swan lamps with batteries? I have heard that three quart Bunsens are sufficient to give a "good light"; but, on the other hand, I am told that 20 are needed to give the bright incandescence, and more than that to produce the full result. The resistance of a lamp and its appendages is said to be 50 ohms when cold; but if so, could three quarts possibly heat it up?—Petro.

[46605.]—**Dynamo Machines Sparking.**—What is the cause of "sparking" in dynamo machines, and what are the "damages"? I have seen some of the large machines at the Palace, when the commutator and brushes were sheathed apparently in electric flames.—Petro.

[46606.]—**Back-Gear Headstock.**—Would some reader kindly furnish a rough sketch, with sizes, &c., of a simple way to make a back-gear headstock, with a mandrel running in gun-metal bushes? Lathe is 5in. centre, and width of bed 3½in.—Progression.

USEFUL AND SCIENTIFIC NOTES.

◆◆◆

Professor Tyndall on Sound, Light, and Heat.—Last week, Professor Tyndall, F.R.S., concluded his short course of three lectures at the Royal Institution on "The Resemblances of Sound, Light, and Heat." He recurred to the researches of Dr. Thomas Young, as themselves illustrative of the close connection between the phenomena of sound and light; the studies of that philosopher on the nature of sound having led up to his parallel studies on the nature of light. The beats in music afforded the most familiar illustration of the interference to which the sound-waves are subject. Such a wave consisted of pulsations of condensation alternating with pulsations of rarefaction. If two waves coincided in such a manner that condensation answered to condensation and rarefaction to rarefaction, the sound became stronger. But if the pulse of condensation in the one coincided with the pulse of rarefaction in the other the sound was neutralised so far, and silence was the result. Experimental proof was given of this periodic reinforcement and extinction of the sound-wave's motion. It was then also shown by experiment that the phenomenon known as Newton's rings establishes a like periodicity as regards light. Newton's main objection to the undulatory theory of light was that it made the shadows impossible. Newton appealed to the fact of the divergence of the waves in water after passing through an aperture, and Professor Tyndall thought a like divergence ought to occur in the case of light. It really did occur, as Professor Tyndall showed by experiment, but the diverging waves obliterated each other according to the demonstrated law of interference. It was further shown that even in water something of the kind took place. In 1808 an observation of Malus ushered in the darkest days of the undulatory theory. Young himself at first felt that it presented an insuperable difficulty, but he wrestled manfully with it, and waited for more light. As yet the notion was current everywhere that the vibrations of the ether were spread longitudinally, like those of sound. At length the idea of transverse vibrations occurred to Young, and he patiently worked it out, undeterred by its involving the paradox of attributing to the ether the properties of a solid. The same fruitful thought long afterwards struck Fresnel, who was then working with Arago. The latter shrank from endorsing so daring an opinion, and that portion of their joint *mémoire* was signed by Fresnel alone. It virtually solved the problem. The remainder of the lecture was taken up with showing experimentally that polarisation was a phenomenon common to light and heat.

Vulcan Cement.—Messrs. Roberts, Adlard, and Co. have drawn our attention to some samples of a new metallic "Vulcan" cement, manufactured by the new Vronheulog Slate Co., of Nantlle, North Wales. The metallic cement is broken into small pieces, and melted over a very slow fire, and then stirred till quite liquid, when it may be run into any desired forms. On cooling it hardens very quickly. One sample, which has been polished, has a finished surface almost equal to that of enamelled slate. The cement is a cheap substitute for bronze, lead, and zinc, at a saving in cost of from 50 to 75 per cent. It can be remelted and recast into any shape or form, and resists atmospheric action and the effects of most acids and alkalies. It may be used most advantageously among many other purposes for jointing gas and water pipes, for packing purposes, for fastening ironwork and glass in wood or stone, for making moulds for concrete, for covering and repairing roofs, for covering walls and protecting from damp, for filling-in defective castings, for making, covering, or lining cisterns, tanks, pipes, baths, &c., and for statues, busts, and all kinds of ornamental and other useful castings, mantelpieces, &c.

On the Alsace-Lorraine railways mineral oil has been substituted for colza in lubricating the rolling stock, with a saving in cost of 60 per cent. The Bavarian lines have followed suit, with the same excellent results.

The Belgian Government is engaged upon a scheme for promoting a complete system of tramways throughout the country, as feeders to the railways, the work to be done by the various communes interested, either singly or in combination, and assisted where necessary by subventions from the State.

There are now 2,195 miles of steel rails on the London and North-Western Railway.

ANSWERS TO CORRESPONDENTS.

◆◆◆

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Tuesday evening, April 4, and unacknowledged elsewhere:—

E. B. Fenessy.—J. L. Wrigley.—H. A. H. Daniel.—Dr. Bond.—David Jones.—F. Chadwick, Jun.—J. Berkeley.—B. and Co.—Britannia Co.—J. Francis.—F. A. Moilliet.—A. J. S.—Chemistiana.—C. S. Stretton.—Carstairs.—Orderic Vital.—D. McKay.—J. C. Brown.—J. W. Fisher.—In Want of Help.—Agricola.—Hum.—W.—Alfojoe.—C. M. R.—Founder.—H.—Working Tom.—Snowball.—T. E. Espin.—An Amateur.—G. J. H.—A. Pumphrey.—W. H. S. W.—A. A. W.—E. E. R. Trotman.—G. E. S.—Fellow Workman.—A. W. Soward.—H. A. Wassell.

W. J. Pollitt. (Your string of questions would require a page for full reply, and you will find most of them answered in back volumes. 1. 30. 2. No. 3. Possibly the Pilsen. 4. Any suitable size, according to the shape required; 11 and 13 millimetres. 5. About 12 hours. Yes, not only unpleasant but injurious. 6. Would do, but not preferred. Commercial acids. 7. Need not be. 8. Depends on how much you make and how much you buy.)—P. J. Farrelly. (Will one of those illustrated on p. 89, last week, do, or do you want a gas-furnace?)—R. T. B. (It has been exhaustively treated in our columns, and that very recently. See Vols. XXXI.—XXXIII. Perhaps Nos. 783 and 784 will give you what you want.)—T. S. (It should be the purest iron—certainly not cast. Bismuth and antimony are the best metals, but German silver is to be preferred to copper. See p. 226, No. 790, and the indices for several forms.)—D. E. H. C. (Write to the Civil Service Commissioners, Cannon-row, S.W. You require a fair knowledge of the ordinary subjects taught at school, a good handwriting, and a special acquaintance with arithmetic.)—A Novice, Birkenhead. (All such alloys contain bismuth; and possibly the cheapest for your purpose is composed of bismuth 8, lead 4, tin 4. That is liquid at 213° Fahr. Ask for some Darcet or Rose's metal at the chemical dealers, and try an experiment. You can make by adding bismuth to plumber's solder.)—Frank Smith. (See p. 109, Vol. XVII., and p. 190, Vol. XV. Anything really good in the line is already on sale.)—Melus. (He can assume what name or style he likes; but should he fall into unforeseen difficulties he must stand his chance of being taken for a member of the "long firm.")—James Pedler. (Have you taken medical advice? Your symptoms, as you describe them, are those of acute rheumatism, and can only be treated properly after personal examination.)—Rex. (If the father's property is personal, the daughter will inherit all; but any real estate will go to the heir-at-law, which, in this case, will be the eldest brother, or his eldest son.)—H.J. Peerlhamp. (We have no recollection of the card. The Birmingham wire gauge is given in inches on p. 14, but there is really no definite gauge. That given on p. 14 tallies with Holtzapffel's list, and approximately with Whitworth's; but wire from different makers varies. If you convert the inches given on p. 14 into millimetres, you will have an approximate measurement.)—Churchman. (A little printer's ink thinned with copal varnish and rubbed in is the best. Clean off with a rag dipped in turpentine or benzoline; or grind up lampblack in copal. Make the marks deep with a blunt chisel. Watts's "Electro-Metallurgy," 2s. 6d., Lockwood and Co., Stationers' Hall-court, E.C.)—R. J. A. (Horse-power means that amount of work which is represented by the lifting of 33,000lb. one foot high in one minute. The terms can be interchanged, 1lb. 33,000ft. high, or 550lb. in one second. 2. We believe it is one shilling.)—An Amateur Electrician, Dublin. (About 20, but the battery fails quickly. 2. There are several, but if that is all you want to know, you can see a diagram on p. 462, No. 878. 3. We do not know, but would suggest an application to the Secretary, Trinity House, Tower-hill, London.)—W. B. H. (What practical utility is the "time" of stop. The distance run is the real test, and we suspect it should be 270 yards, not seconds; but no official record has been published.)—A Traveller. (How can anyone answer questions so vague? Probably your suggestion is correct.)—Tat. (They are bent round pins placed in a board just where the bends are required. The coil is done on a mandrel.)—Electro. (You will find the most complete details in back numbers. See the index, issued March 24, and p. 33, No. 808; p. 103, No. 811; p. 458, No. 747.)—J. R. (You must have a top joint, which any musical instrument dealer ought to be able to get.)—Tyro. (See p. 41, No. 808, and many replies in back numbers. We do not like to discourage you, but a locomotive boiler is really a difficult job, and as you have to ask what tools are necessary, we would suggest a trial first of something more simple.)—A Poor Deaf Lad. (Cannot possibly be answered without personal examination. From the fact that you can hear better at times, the probability is that there is some mechanical obstruction. You are sure it is not an accumulation of wax?)—W. G. S. (We do not know of any book which gives such examples. What is the utility of the rule in such questions, which crop up only now and then, and are worked out in a few minutes?)—Fish. (There is a book by F. Vizetelly which enters into the question, but we forget the publisher.)—Apprentice to a Fitter. (A pair of dumb-bells, and gentle but constant exercise at spare intervals, will answer your purpose.)—Mirror. (The glass must be thoroughly clean; then on a flat table covered with baize place a sheet of tinfoil. Pour the mercury on that, and quickly spread it over the surface. Then slide the glass plate on so that its front edge drives a little ripple of the surface mercury in front. Weight down, and leave for a day.)—Guy Fodge, Belfast. (We know nothing of the "School of Telegraphy" named.)—Tasmania. (The disorder is a comparatively rare one, and personal examination by a medical man absolutely necessary. Dr. Edmunds could not give you any advice, and would, we know, decline to do so if we inserted your query.)—H. Sheriff. (If you had repeated the queries we could have replied more definitely. If they have been sent before, they have not been inserted, either because their proper place is the "Sale Column" or the subjects have been dealt with in former volumes. Send again; but before doing so, run your eye down the last published index.)—J. R. Leigh. (Two cylinders, one each side; both drive on the one crankshaft. One can be made to work by a little manœuvring.)—R. B. W. (Evidently constitutional, and advice only possible after personal examination.)—Veritas. (Yes, the distance has varied within the last six months. It is greater in winter than in summer; but for all purposes you may say it is 92,000,000 miles.)—H. C. (The later form of the first named is still protected, and so is the second one.)—T. (It is universally distributed within a height of, say, half a mile from the surface. It is found on the Atlantic and on the tops of the Alps, and is there called cosmic dust; but in dwelling-rooms and factories it exists in much greater quantity. Its nature depends on the locality—mainly organic in the flax or flour mill, mineral in a coal-mine and on the Atlantic, mixed in dwelling-rooms.)—J. S. Rochard. (1. Yes. 2. Nothing. 3. Possible, but at the risk of an action, for a patentee must declare that he has "invented" or that he has received a communication from some one abroad. 4. The clock is only a detail. We do not know that it is claimed as part of the patent.)—W. H. (Bathing in hot water is the best remedy, and some add bran or hay. See the indices of back volumes.)—D. David. (Yes, any of the makers of woodworking machines can supply such a machine.)—Faker. (Yes, the water does not injure the rubber because the latter is vulcanised.)—Hopeful. (12s. 6d., post free. Yes, Kent and Co., Paternoster-row, 1s. monthly, we believe.)—White Swan. (Would do to charge a secondary, but has scarcely sufficient E.M.F. for lighting purposes.)—J. H. Anderson. (Paraffin wax is the best, we believe.)—F. G. (You mean a dye, we presume. All preparations of the kind are based on one of three things—viz., a silver salt, a salt of lead, or the juice of green walnut shucks. With the silver salts it is almost impossible to avoid staining the skin, unless it is carefully covered with pomatum. Lead is objectionable, as it kills the hair, and walnut juice is not always obtainable. Perhaps the simplest and best is to moisten the hair, previously protecting the skin, with a solution of nitrate of silver (1 to 8 parts of water), and then with a weak solution of sulphhydrate of ammonium. That is an instantaneous process, and is as good as any.)—Subscriber, Rotherham. (Just the thing to be struck. See that the sheet-iron pipes are connected to a good earth-plate by an iron rod not less than 1in. diameter. Read the article on the Lightning-rod Conference on p. 441, No. 877.)—Young Mechanic. (The City and Guilds of London Institute, and the Whitworth Scholarships in connection with the Science and Art Department. Where do you live that there are no classes in your town? Particulars as to the City Institute of the director, Gresham House, E.C. The Whitworth prospectus can be obtained from the Sec. of the Science and Art Department, South Kensington, S.W.)—Digit. (See pp. 15, 16, No. 885, and a table, p. 410, No. 797.)—Amateur Electrician. (A simple one given on p. 452, No. 825; but why not endeavour to see one?)—Zadig. (Mix with solution of alum instead of water. It takes longer to set. May be plainly coloured, but scarcely marbled.)—W. A. H., Manchester. (Any oil, almost—say cotton-seed. 2. No French chalk at all if you wax the mould; but the sellers give the proportion they recommend. You can dust the type with the chalk if you clear the faces. It sticks because not properly oiled. 3. A hot solution of soda and a brush will do all the cleaning necessary. 4. Depends entirely on the heat. A little practice will show you. If you leave it too long, the rubber becomes too hard. How do you bed the type in taking your cast?—perhaps you make that too deep.)—Regulas. Marine glue is best, but Berlin black, thinned with turpentine, is good, as is also paraffin wax.)—Erin-go-Bragh. (Mix the rubber with sulphur; but it is better to buy the stuff ready prepared.)—Dr. Royston Pigott. (Shall be pleased to receive the contributions mentioned.)

THE LATE "SECONDS' PRACTICAL WATCHMAKER."

Since remitting the amount subscribed up to last week to Mrs. Coates, we have received a few more subscriptions. We will add any further contributions that may reach us, and remit the amount as soon as it is worth sending.

The decrease in the number of second-class passengers, and the receipts from them, continues on the London and North-Western Railway, but at present Mr. Moon does not think it advisable to do away with that class.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.

[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive. 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

Throat Irritation.—Soreness and dryness, tickling and irritation, inducing cough and affecting the voice. For these symptoms use Epps's Glycerine Jujubes. Glycerine, in these agreeable confections, being in proximity to the glands at the moment they are excited by the act of sucking, becomes actively healing. Sold only in boxes, 7½d. and 1s. 1½d., labelled "James Epps and Co., Homœopathic Chemists, London." A letter received:—"Gentlemen,—It may, perhaps, interest you to know that, after an extended trial, I have found your Glycerine Jujubes of considerable benefit (with or without medical treatment) in almost all forms of throat disease. They soften and clear the voice.—Yours faithfully, Gordon Holmes, L.R.C.P.E., Senior Physician to the Municipal Throat and Ear Infirmary."

Holloway's Ointment.—A Cure for all.—This unguent may be rubbed into the system, so as to reach any internal complaint. By this means it cures sores or ulcers in the throat, stomach, liver, spine, or other parts. It is an infallible remedy for bad legs, bad breasts, contracted or stiff joints, gout, rheumatism, and all skin diseases.

OUR EXCHANGE COLUMN.

◆◆◆

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

◆◆◆

Lathe wanted, in exchange for a Mahogany Biunial Limelight Dissolving View Apparatus, in perfect order.—Nicholl, Castle-lane, Belfast.

Scientific Instruments wanted in exchange for Oleographs, Chromos, or Picture Frames.—Nicholl, 29, Castle-lane, Belfast.

Organ Bellows and Windchests, several in good condition (ready for wind and pipes); books, musical instruments, or offers to W. Johnson, 12, Moxley, Wednesbury.

Slide-rest, 3½in. centre, nearly new. Exchange for stocks and dies, Whitworth gauge.—W. Simkins, 48, College-street, W., Camden Town, N.W.

Wanted, Screw-Cutting **Lathe**; will give part cash and another lathe.—H., 4, Sugden-road, Lavender Hill, S.W.

Large Plate **Electrical Machine** (3ft. diameter), conductor and stool, in exchange for other physical or chemical apps., or tricycle.—Lecturer on Physics, Central Science Schools, High street, Marylebone-road.

Heliostat.—Very massive new brass Heliostat, for solar microscopy, with mirror, double-motion screws, &c., weight 12lb., cost £5; exchange for microscopic or other scientific apparatus.—J. L. M., 106, Princes-street, Edinburgh.

Large **Cylinder Machine,** broken, Leyden Jars, splendid black Cat Skin, 20 zinc rods, 1lb. each, 10 small Bunsen Cells, 20 Porous Pots, &c. Wanted, ½-plate Portrait Lens.—H. Fell, Market Rasen.

Hydraulic **Pressure-Gauge,** indicates 4 ton, good conditon. Exchange for small Gas Stocks and Dies, or other offers.—22, Coventry-road, Hinckley, Leicestershire.

Will exchange "**Book of the Pigeon.**" "Book of Canary and Cage Birds." 4 Sebright Bantams, and 6 Fantails; for Chemical Balance, Apparatus, or Tricycle. Worth £8.—Jno. Dunlop, Dornock Public School, Annan.

Fretwork Machine new, prize Holly; exchange for violin and bow.—W. T. Kent, 68, Westbury-street, Swansea.

48in. **Bicycle,** set of castings for 2in. engine, 5ft. gap lathe-bed planed, leading screw, full set of change wheels; exchange, what offers?—R. D. Smith, 12, Fazakerley-street, Chorley, Lancs.

Lathe wanted, 4 to 6in., rests, chucks, screw-cutting or otherwise, cheap, also drilling machine; exchange small canoe. Ashenden, Chartham, Canterbury.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

◆◆◆

For Sale.

"**The Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—F Robertson, 13, Greek-street, Soho, W.

Band Primo.—A Tutor for all Band Instruments. "A Book which every Bandsman should have." Price 5s., P.O.O. T. Rawson, 114, Heaton-lane, Stockport.

Metallic "E" **Violin Strings.** Infinitely superior to Gut. Three, post, 1s.—Smith, 2, Bedford-street, Plymouth,

Incrustation Prevented. When other means fail, Morgan's Boiler Compound is highly recommended.—W. H. Morgan, Engineer, Gloucester.

The **Britannia Company's** new No. 13 Screw-cutting Lathe, 30in., strong and accurate, price £15 15s. See notices in English Mechanic. Apply for circular, 1 stamp.—Britannia Company, Engineers, Lathe Makers to the British Government, Colchester, England.

Launch Engines, new, different sizes, cheap.—State size required.—John Middleton, 16, Hope-street, Glasgow.

Lathe, 3½in. centre, 3 foot, screw-cutting. change wheels, compound slide rest, nearly new, £10. Makin, Cupola, Sheffield, great bargain, good tool, warranted perfect.

Elastic Stockings. No makers in London. Made in Liverpool only by Smith and Sons, Breck-road.

Parkinson's Amateur **Polisher's Cabinet.** The most inexperienced can polish with success. Circular free.—James Parkinson, Warrington.

Japanning done for the trade. Machines of every description.—Merson and Co., 44, Wynyatt-street, E.C.

Bicyclists, Athletes, and Engineers should wear the patent nickel-plated steel Albert, new and elegant pattern, always retains rich polish. Does not rust. Post free 12 stamps.—Gorse, 128, Moor-street, Birmingham.

"**Fiddler's**" double soundboard **Violin,** loud and clear, 10s.—"Fiddler," 19, Edward-street, Burdett-road, E.

Paints.—Instructions for Making Paints suited for the grinder and operative painter.—T. Armstrong, Woodville, Hounslow.

Bachelor's **Brass Buttons.** No coming off. No sewing. Last lifetime. Packet free, 14 stamps.—Hezmalhalch.

Excruciatingly **Comic Readings.** You will be obliged to laugh. Send 1½d. for one, and rejoice.—Hezmalhalch.

New "Eclipse" **Pipe.** No oil in mouth. No smoking wet tobacco, 2s. free.—J. Hezmalhalch, 1 Fellisclifle, Leeds.

Two 10in. silvered **Glass Mirrors** to be sold for a very reasonable price, one of finest quality by Calver, with tube, flat, finder, focussing eyepieces complete, but without stand. What offers?—Apply Rev. W. G. Matthews, Rectory, Wadebridge, Cornwall.

The **Dental Wonder,** a marvellous cure for toothache, post free, 1s. 2d.—Southwell, Pharmaceutical Chemist, Boston, Lincolnshire.

Southwell's Absolute **Remedy** for Tic Douloureux, post free 2s. 9d.—Southwell, Pharmaceutical Chemist (by examination), Boston, Lincolnshire.

Munroe American Organ **Tubeboards** with reeds voiced. Few only.—Ray, 86, Poplar Walk-road, S.E.

Microscopic Objects for mounting. Sample 20 preparations and price list, 1s. 2d.—R. Philip, Grove-street. Stepney, Hull.

Sufferers from Indigestion, &c., should read Dr. Brearey's "Popular Treatise" on that subject.—Address the Author, enclosing 7 stamps, 1, Belle Vue-square, Scarboro', for copy.

Fisher's Ethoxo-hydrogen **Limelight Apparatus** gives the most brilliant and whitest light. Perfectly safe.

Ethoxo-hydrogen **Generator,** made in copper, price 30s. Send stamp for particulars.—Fisher, Calverley-street. Tunbridge Wells.

Ingredients for preparing Hop Bitters, 6d. per packet, post-free, 8d.—Jones, Chemist, Westminster-road, Liverpool.

Elegant Ladies' Gold **Rings,** 5 stones, diamonds and sapphires, diamonds and rubies, or all diamonds, 15s. each. P.O.O. to A. Francois, care of E. Charles, Ryland-road, Birmingham.

Patent **Eye Pretectors,** 12 stamps; to A. Francois, care of E. Charles, Ryland-road, Birmingham.

Pianista, quite new, an instrument for playing the Piano or Harmonium automatically, cost £32 10s., can be seen after 6 p.m.—18, Bedford-street, Choumert-road, Rye-lane, Peckham.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, APRIL 14, 1882.

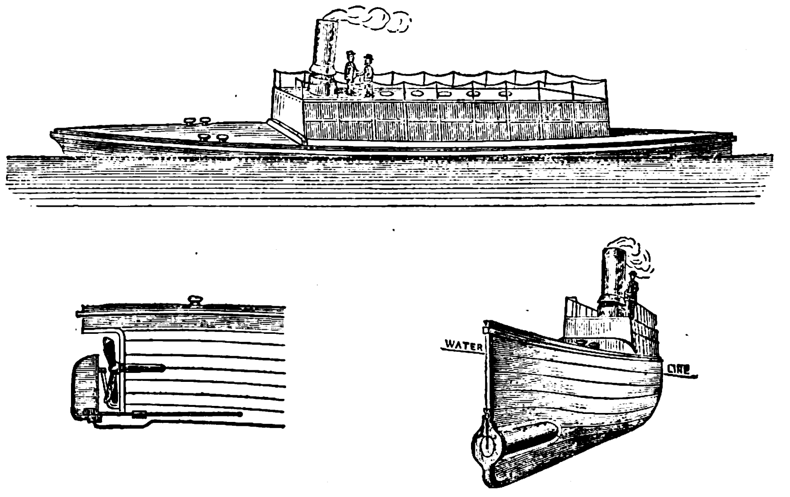
THE NAVAL AND SUBMARINE EXHIBITION.

THE Naval and Submarine Exhibition, opened last Monday at the Agricultural Hall, must be considered a decided success. Thanks to Mr. Samson Barnett, jun., Londoners and visitors from the provinces have now an opportunity of forming for themselves a tolerably clear idea of the value and variety of the means and methods employed in the mercantile marine, and of the various appliances for traversing the sea in comparative safety and comfort. Of actual shipbuilding itself, there is little to be seen beyond the models sent by Lloyd's Register, but everything else that can be supposed to appertain to the great carrying trade of the world is exhibited—from the furniture and fittings of the ships, to all those appliances and minor details which help to make a modern steam-vessel a little world in itself. As far as the general sightseeing public is concerned, probably the most interesting exhibit is that of Mr. Samson Barnett—a large diving-tank, 20ft. in diameter and about 12ft. deep, with a number of plate-glass windows, through which the operations carried on can be watched. That occupies the centre of the ground-floor, and around it are arranged the stalls of the various exhibitors of diving apparatus and other appliances used in submarine work. At regulated intervals during the day operations of various kinds will be carried on under water in this tank, including an exhibition of the skill and ability of a party of sponge-divers from the Levant, who have, by long practice, acquired a power of staying under water for a time which seems extraordinary. The utility of the Fleuss helmet, which we illustrated and described in No. 792, p. 272, will be practically demonstrated, as an improved diving appliance which relieves the diver of the incumbrance of pipes, and permits of the greatest freedom of motion under water. The helmet, it may be remembered, contains compressed oxygen, which is used to revivify the expired breath, the carbonic acid expelled from the lungs being absorbed as the expired air passes through a chamber packed with broken porcelain wetted with caustic soda. The helmet has already done good service, notably in the Severn Tunnel, where a diver was enabled to walk many yards up the submerged workings, and do some absolutely necessary work that would have been impossible if he had to drag the air pipes of the ordinary diving equipment with him. The Fleuss helmet is also of great utility in colliery explosions, and thus competes with the Denayrouze apparatus, which is also exhibited and shown in work as a submarine appliance. The apparatus of Messrs. Fleuss, Duff, & Co., Applegarth and Denayrouze, are fitly supplemented by Messrs. Barnett and Foster with a collection of improved diving appliances, and Foster and Fleuss's submarine and mining lamp, while Messrs. Siebe and Gorman, and some other firms, also show approved and tested apparatus. We may here say that it is impossible, in the space available, to give the names of all the firms exhibiting, which in the catalogue occupy, with a bare enumeration and brief description of their exhibits, nearly 200 pages. We can only mention names where they seem absolutely necessary for the purposes of identification. Passing the diving apparatus, the next most attractive exhibit will probably be the models of ships, and here we find a very complete collection. The Admiralty show the *Monarch*, the *Devastation*, and the *Polyphemus*, with a Russian Popoffka, or circular ship, while amongst celebrated mercantile steamers we have large-scale models of the three latest Transatlantic liners, the *Servia*, the *City of Rome*, and the *Alaska*, the last named of which has recently made the remarkable passage between New York and Queenstown of seven days, six hours, forty-three minutes—the best on record. Close at hand we have the *City of Berlin*, the *Britannic*, and the *Lydian Monarch*, the latter chiefly noticeable as a sister-vessel to that in which Jumbo was shipped to the United States; but we must not forget the *Stirling Castle*, a tea-clipper, which recently on her trial attained a speed of 18½ knots, and is amongst mere trading vessels the fastest steamer afloat. In the division of ships, there are many models and half-models of yachts which are sure to attract the attention they deserve, and amongst them may be noted a nicely finished model of the late Czar's "yacht" *Livadia*, noticeable as an experiment in naval architecture which is not likely to be repeated. Leaving the models, we will turn our attention to what may be termed the novelties of the exhibition, and these are found mainly in rotary engines, which have lately come to the fore in a rather unexpected manner. Practically condemned by engineers and by Reuleaux in his celebrated treatise, they have, during the last two or three years, pushed their way into notice, partly by reason of certain demands, partly because they are really useful motors. First and foremost, by reason of its size, we notice the large rotary of M. Brossard, which is said to be of 1,000 horse-power, but which unfortunately arrived too late to be shown in working order. This machine, which would require at least a page to adequately describe it, is of the type in which one cylinder is placed excentrically inside the other, and forms the revolver or roller of the engine. The "piston" is attached to the main shaft, and passes through a slot in the small or inner cylinder, which it obliges to rotate round an excentric axis. The steam enters the large cylinder at the bottom (that is, one of the sides, for the engine is of course horizontal), and the small cylinder through the shaft carrying the piston, an arrangement by which the area presented to the steam in the two cylinders is always the same whatever may be the position of the piston. The engine has an ingeniously worked out governor, which controls the speed either by regulating the degree of expansion or by throttling the steam; but we shall doubtless hear more of this engine when it has been fairly tested, and it must suffice to say that the inventor claims economy, simplicity, easy manipulation, and the minimum of wear and tear, with absolute regularity in working. Hodson's rotary is now well known from its performances at the Crystal Palace, where one is shown running at 1,000 revolutions a minute. The shaft carries a piston which is driven round the cylinder by the pressure of the steam until it reaches the exhaust, the steam being admitted by means of a flap. As the piston passes the exhaust, it closes the flap, which falls immediately afterwards, and admits steam to one side only, the admission being regulated by a cam on the shaft operating the throttle-valve. These engines, which are shown driving a De Bay fan, work excellently, and the only suspicion about them is their durability—*i.e.*, whether wear and tear will not be excessive. That, of course, remains to be proved. Another rotary engine at the exhibition is made by Mr. Dexter, of Bourne End, near Maidenhead, and is especially adapted for winches and slow work generally, though it can be utilised in launches. This engine consists of a cylinder with a roller and slides, the latter actuated by cams on the cylinder covers. The division between inlet and exhaust is passed by the slides rubbing against a steel spring, and as the details have been well considered, the wear has been reduced to a minimum. The engines reverse with a slight motion of a lever, and can be made to run at any desired speed. Amongst propellers we noticed exhibits claiming superiority over the ordinary forms, but in the absence of practical trial—the only safe guide in this matter—there is little to be said. The only real novelty is Welton's fan propeller, exhibited by Duncan Brothers, applied to a launch. In this device, instead of the shaft having a rotary motion, it reciprocates and works a couple of fan-blades which close in as the shaft is withdrawn and spread out as it is driven backwards, thus giving a direct pushing motion. In this case, as in all others connected with propellers, it is only practical trial which can determine the relative merits. In the tank-room Mr. J. Neal exhibits a boat in which the propellers are placed amidships, with tanks into which they can be drawn up when desired. The propellers, of the ordinary screw form, are thus placed in the solid water beneath the bottom of the vessel, and may consequently give an advantage which is not to be obtained in the usual position. Boat lowering and detaching gear is well represented; but we failed to find anything superior to the devices shown at the exhibition held at the London Tavern in April, 1873, an account of which we gave in No. 422, p. 131. As a matter of fact, many of the most successful boat lowering and detaching gears are merely modified or exact counterparts of those exhibited nine years ago; but that is not to be wondered at, for it takes a long while to establish the reputation of any new device of the kind—*e.g.*, the Berthon collapsible lifeboat, which is here shown in action. This boat, which packs up into a small space, and can be stowed along the bulwarks, so that an emigrant vessel might carry sufficient for all her living freight, was illustrated and fully described on p. 194, No. 424. Of detaching gears, we may say that they divide into two groups, in both of which slip or tumbling hooks are used, the difference consisting in the manner of letting them off. In this connection considerable divergence of expert opinion exists, some nautical men holding that the boat should not be released except by the movement of a lever in charge of some responsible officer, while others hold that it is preferable to make it self-releasing as soon as it is water-borne. The other differences between the various designs are mainly in matters of detail; in the first kind the usual arrangement is a rod running along the bottom of the boat connected to the hooking-tackle in such a manner that when moved by a lever both hooks must be simultaneously released; in the other kind the hooks are generally so contrived that on being relieved of the weight of the boat they automatically open and release the boat.

Amongst the machinery exhibited, the steam stearing-gear will have most attraction for nautical men, and probably also for shipowners, though some of the latter will no doubt examine with interest the refrigerating machines, comparatively new devices, which have already rendered possible the importation of meat from Australia, and which promise to create a large trade in the transport of perishable commodities of all kinds. Of the smaller sized marine engines nearly every good type is shown by a number of different makers; but for obvious reasons the engines of large ocean-going steamers are shown only in model form. Fox's corrugated boiler tubes are, however, exhibited in full size as applied to large marine boilers. Boilers, especially of the portable kind, are shown in great variety, and many of them are under steam, while boiler fittings are exhibited almost in profusion. Rudders are represented by well-known devices, and amongst them will be noted that of Capt. Heathorn, R.A., who uses two rudders, which can be opened one against the other, thus checking the way of the vessel. The inventor claims that the device, by using the deflected current of ejected water from the screw, doubles the power of steering, and enables the vessel to be steered when going astern. Two models are shown, one with a screw propeller working in a case, the other being a *facsimile* of the rudders as applied to a launch propelled by a jet of water through the sternpost. Amongst the models of lighthouses is a large-scale reproduction of the celebrated Galley Head lighthouse, which is under the control of the Commissioners of Irish Lights. Life-saving appliances in the form of rafts, buoys, dresses, mattresses, &c., are exhibited in great variety, and in connection with these and the lifeboats, two prizes will be awarded, after trial, by a committee consisting of Vice-Admirals H. Boys and A. W. A. Hood, C.B., assisted by Sir Digby Murray, Bart During the exhibition several lectures on subjects connected with naval and submarine engineering will be delivered, and these, together with selections from the papers read, and a number of special articles, will be published in a large edition of the catalogue, to be issued after the close of the exhibition.

THE BRITISH NAVY.*

THE first volume of Sir Thos. Brassey's interesting account of the British Navy has been rapidly succeeded by the second, which treats of miscellaneous subjects—armour, guns, unarmoured ships, harbour defence, torpedoes, &c. We gave a lengthy notice of the first volume, which dealt with the fighting ships, on p. 557, and we have now to review what Sir Thos. Brassey says as to the details of their construction and armament, so far as concerns armour and guns. The statistics given as to the relative strength of the British and foreign navies, represent the situation as it existed two years ago, when the work was mainly written; later details will appear in subsequent volumes. The chapter on armour and armour experiments is shorter than might have been expected, if we did not remember that the latest experiments usually rob their predecessors of much interest. Still, in something less than 30 pages the author has contrived to compress an account of the most important experiments, with illustrations, and to give views of the *Huascar*, after the engagement which led to her capture by the Chilians. The figures show the development of armour from the early *Warrior* to the trials at Spezzia on plates nearly 22in. thick. The second chapter deals with guns and gunnery, and incidentally with powder. The illustrations in this portion of the book give a good idea of modern heavy guns, as besides the 80-ton gun we have the new type of Woolwich breech-loader to compare with Krupp's enormous weapons and the system adopted by the French. The burst 100-ton gun of the *Duilio* and the experimental bursting of the *Thunderer's* gun also find appropriate places, as do the diagrams showing the penetrating power of the British muzzle-loading, and the French and German breech-loading guns. These are all taken from recognised authorities, and are duly acknowledged. Probably the most interesting chapter in the book is that on torpedoes and torpedo boats, which will, in the opinion of many competent judges, play a more important part in naval fights of the future than either armour plates or big guns. In his historical account Sir Thos. Brassey does justice to the claims of the Americans Bushnell and Fulton, who first invented "diving boats" for the purpose of affixing torpedoes to the bottoms of vessels. Submarine mines probably have their origin in Bushnell's idea; but little appears to have been done with them until in 1839 General Pasley blew up the wreck of the *Royal George* by means of powder fired by electricity. Nobell about 1841 sold an invention of the kind to the Russian Government, and in the same year Colonel Colt, who had been experimenting on Fulton's lines, completed a system the utility of which he publicly demonstrated in New York Harbour in 1842. The first instance of the use of the subaqueous mine as a means of protecting channels in time of war was in 1848-50, when Prof. Hinly laid a line of mines across the harbour of Kiel, to prevent the Danish war-ships entering. In his case the mines consisted of strong casks made water-tight and filled with gunpowder, which was to be fired by an electric current. One of these mines was picked up in 1873, and was found to be in a remarkably perfect condition. The mines were never actually brought into use, nor was the submarine boat, built at the time from the designs of a Bavarian named Bauer. During the Crimean war, two kinds of mines were used by the Russians—one exploded by contact with the ship, the other by an electric current sent from the shore. Although these mines did something to check the action of the Admirals, and rendered Captains very cautious, no effective service was rendered by them, for when they were not removed by the boats sent to fish for them, they either failed to explode, or did so in a manner that caused little damage. In 1859 the Austrians employed submarine mines of gun-cotton, to defend the entrance of the Malamocco at Venice, and devised a means of ascertaining when a vessel was within range of the mine, which, however, was useless on dark nights, or while smoke from guns hung about. It was not until the American War of Secession that torpedoes gave any practical illustration of their efficiency as weapons, both of offence and defence, and it is remarkable that although the heaviest artillery then known was used for the first time, not a vessel was lost, and a few only were materially injured by shot or shell. The losses, which included ironclads and wooden vessels, were all brought about by submerged torpedoes, some of which acted by contact, others being fired by electricity, while, for the first time the spar torpedo was brought into use. In nearly all cases the fuse devised by Prof. Jacobi for firing was employed in contact torpedoes. It consisted simply in a glass vessel containing sulphuric acid, which, escaping when the containing vessel was broken, found its way to some chlorate of potash, and thus ignited the powder. In the war between Brazil and Paraguay, in 1866, the defenders resorted to the use of submerged torpedoes to stop the advance of the fleet up the river Paraguay, and tried, without success, to blow up the vessels by means of floating torpedoes. An ironclad, which had been ordered to advance, however, struck a submerged mine, and was broken in two. In the Austro-Prussian War of 1866, an elaborate system of torpedo defence was devised for the protection of the boats on the Adriatic, but no opportunity of testing the efficiency of the mines occurred. An invention of Baron von Ebner combined the advantage of the electrical and the contact system, and left explosion optional on the part of the defender. In this arrangement nine percussion knobs, projecting above the cover, received the shock by means of bars on a horizontal wheel, the axis of which carried the electric fuse. The turning of the wheel put the fuse in circuit, and at the same time brought into action a current of a higher tension which was more suitable for inducing ignition. In the war between Germany and France in 1870, torpedoes were prepared by one of the combatants, but they were not actively employed. The results of the torpedo fighting in the Russo-Turkish war are too well known to need mention; but a record of them will be found in Sir Thos. Brassey's book, which is intended to be an historical epitome of the progress of the arts of naval war. So far as actual warfare is concerned, the various forms of torpedoes intended to be used offensively have almost a blank record, except the spar-torpedoes worked from boats, which must of necessity run some risk while approaching the enemy. The most remarkable invention of the kind is the "Fish" torpedo, which contains within itself the propelling and firing gear, and is apparently as perfect as such a machine can be, though there is no reason to suppose that its powers have been fully developed. Invented primarily by Commander Lubis, of the Austrian navy, it has been perfected by Mr. Whitehead, and the "secret" has been purchased by several Governments. The charge is from 33lb. to 55lb. of gun-cotton, and a mere graze is sufficient to cause an explosion. Hence,



ERICSSON'S TORPEDO BOAT, "THE DESTROYER."

---

* The British Navy: its Strength, Resources, and Administration. By Sir Thomas Brassey, K.C.B., M.P. Vol. II. London: Longmans.

the trigger setting the screws in motion is only pulled as the torpedo leaves the firing tube, and it is not until some distance has been traversed that the machinery itself releases the last safety-pin preventing the accidental firing of the explosive. The fore part of the torpedo contains the explosive, the after-part the motive engines, while the centre is the "secret," the means whereby the missile is made to automatically regulate its depth according to the degree of immersion required. This is accomplished by horizontal rudders, but the method of actuating them is the secret. It is believed to be done by the pressure of the water acting on the ends of the chamber and on a spiral spring, which is set to suit the required depth, and the motion of which, by means of a rod, shifts the horizontal rudders. The amount of regulation can be arranged to the greatest nicety, for after the compressed air, which drives the screws, has expended itself, the torpedo may be made to rise to the surface or sink to the bottom, and further, if loaded, the safety apparatus can be arranged to prevent the explosion, and thus facilitate the recovery without risk. The engine is of the Brotherhood type, and is worked from a reservoir of air charged to a pressure of 1,000 or 1,200lb. The Lay torpedo, which appears to be more complicated than the Whitehead, is propelled by ammonia at a pressure of 40 atmospheres, and is complicated by trailing an electric wire at the stern, which, however, enables an electrician to direct its course, and to fire at the proper time. The Ericsson torpedo is worked by sending compressed air through a hollow cable; but owing to the weight of the latter, the "range" is at the outside only a few hundred yards. Two other so-called automatic torpedoes have been invented—one by Capt. MacEvoy, the other by Commander Howell, U.S.N. The former is carried at the end of a spar until near enough to be launched, the motive-power being carbonic acid released by the action of an acid on a carbonate; the latter derives its movement from the "inertia" of two heavy iron wheels which, just before starting the torpedo, are revolved at speeds of about 4,000 to 10,000 turns in a minute. Captain Ericsson has within the last three years devised an improved form of torpedo, which is fired from a special vessel called the *Destroyer*, having a fine wedge-shaped bow and stern, and an intermediate curved deck from stem to stern, which supports a heavy armour plate about 32ft. from the bow inclined at an angle of 45°. The vessel will be deeply immersed when in fighting trim, a deck-house being riveted water-tight to the upper part of the hull. There are some other peculiarities about the vessel which render her different to other ships which have been built specially for firing torpedoes. We are indebted to Messrs. Longmans for the engravings on the opposite page. Torpedo launches and torpedo boats are fully described, and many pages of the work are devoted to unarmoured cruisers and to "mercantile auxiliaries," illustrated by a couple of plates and several diagrams of the *Servia* and the *City of Rome*. This portion of the book is full of interesting details in connection with a subject which lately, thanks to Sir W. Armstrong, has attracted much attention, and received much elucidation at the recent meeting of the Institution of Naval Architects.

WATCH-CLEANING AND REPAIRING.

By "A Fellow-Workman."

(*Continued from page* 95.)

NOW you will naturally suppose that a mainspring, being a strong, sturdy fellow, is perfectly able to look out for himself; but if you do, you will soon get mistaken. I assure you that the mainspring requires as much attention as the balance. I do not say that it gets out of order as easily, but I mean that it requires as much care in repairing; the hole for the rivet or catch (as described last week) should be perfectly in the centre of spring, and when in the box you should see that the spring should not come high enough in the barrel to press against the lid or cover.

I have also seen some jobbers who have a way of pulling the mainspring out straight, and then letting them spring to again; also pulling it up like a spiral spring, and pulling it about like a piece of indiarubber. Now, I cannot see what possible good this can do the spring. I think it must weaken it, and in some instances of common springs, cripple it; so I would advise you not to pull it about more than is necessary. I have got some very funny ideas about the mainspring—I actually don't believe in oiling it; in fact, I have tried it in many instances of troublesome watches of different kinds, and have found that the watch will go longer between cleanings, and keep better time. I clean it first with paraffin oil, then with chalk, and don't leave off until I get it perfectly dry and clean; then I clean the barrel and arbor, put a little oil to the pivot of the arbor, and leave the spring dry.

Chain.—The amateur generally finds the chain very annoying—so did I when I first began; but as soon as my master told me how to do it, I found no difficulty whatever. I will tell you what he said:—I had jumbled up about five links, and the master, who was looking over my shoulder, said, "Let's look at your punch—that's too large." So he brought me four punches of different sizes, told me to take the smallest one, which he called the "starting punch." Now this was a very small one, made from a sewing-machine needle; the point had been removed on the oilstone, and was perfectly flat (this is done by holding the needle in the left hand, and rubbing a piece of oilstone, which is in your right hand, in a French-polisher's fashion over the point of the needle). "Now," said he, "put the point of your punch on the centre of the leaf about where you would suppose the rivet to be, and tap lightly with your small hammer. Now watch your rivet. Does it move?" "No," said I. "Tap a little harder," said he. "Does it move?" I could just see it breaking away, and I said so. "Now," said he, "just take a punch a little smaller than the rivet: you can see where to put it, and tap lightly." I did so, and the rivet came out clean, and since that I have never found any difficulty in removing a rivet. The chain should be laid on a piece of boxwood, with the oval side upwards, so that the rivet runs with the grain of the wood; use small piano wire, or wire sold on purpose, nip off close to the top, leave ⅛in. at bottom, then take hold of this ⅛in., close to the chain; with your nippers, nip half-way through, rivet top end while in the nippers; continue gently to squeeze the nippers while you lightly tap the top with a small hammer; continue to tap and squeeze until the chain drops from the face of the nippers. Now remove any part of the rivet that protrudes beyond the surface of the chain, polish and burnish, and it will be difficult to tell which rivet you put in. You must be careful to see that both the hooks turn the same way before you put the chain together.

The stop-work very seldom gets out of order of itself, but the spring sometimes gets ruptured in cleaning: you must always try it after you have cleaned it, to see that it works properly before you put it together.

Motion Wheels.—These wheels seldom require any repairing; the steel wheel is called the "cannon pinion,"—this carries the minute-hand; the next is called the "motion-wheel," the next is called the "hour-wheel,"—this wheel carries the hour-hand.

Dial or Face.—If you should have to fit a new dial (send the old one as pattern), put it in its place, take a needle, and mark for holes in stump to be drilled, and make a small hole with a pivot drill; see that the hour-wheel has got a little shake—if it has got too much, put on a "paper washer"; if not enough, turn back the shoulder by placing it on an arbor in the turns. Be careful and don't cut off the pipe.

Hands.—The hour-hand only wants putting on if you have the right size; if you are put to the push, you can sever the pipe; there are small square files made on purpose for fitting minute-hands. To hold the hands while filing, I make a notch in both jaws of a pair of old pliers. In these you will be able to hold the body of the hand while you are enlarging the square; the holes in second hands are made with a watch broach.

Glasses.—There is not much difficulty in fitting flints or double lunettes; but if you have a hunter, you will find a little difficulty; in any case the glass must not touch the centre-pinion.

This is the end of the "general repairs" for a verge watch. I will next deal with the "extra repairs," to the best of my ability.

(*To be continued.*)

THE INDUCTION COIL AS AN INSTRUMENT OF RESEARCH.—I.

1.—Introductory.

MUCH has been written, both in the pages of the English Mechanic and elsewhere, upon the subject of the construction of induction coils. Coils of all sizes, and of every imaginable pattern of build, have been described in all their minutest details. The relative merits of different methods of winding and of insulating, the claims of mercury and of platinum contact-breaks, the respective advantages and disadvantages of various forms of batteries, have all been so fully discussed that it seems almost impossible to find anything fresh in connection with coils about which to write. But notwithstanding all this talk concerning the making of coils, little has been written on the use of a coil when made. It seems usually to be considered by writers on the subject, that the object of a person who sets about to build a coil is to give himself a certain amount of amusement in the mechanical process of its construction, and when made, to provide himself with a little more amusement by lighting up a few pretty vacuum tubes, or by irritating the nervous systems of his too-confiding friends.

It is to supply this deficiency, to show that the induction coil is not a mere toy, to show that it is a powerful instrument of research in perhaps one of the most fascinating branches of science—that of molecular physics,—to tell the story of some of the discoveries that have been made by its aid, that these articles are written.

But what is an induction coil? What are the essential parts of it? What is its action? And why does it so act? These questions meet us at the outset, and unless we clearly understand the answers to them, it will be impossible for us ever to attain to a just appreciation of the use of the coil as an implement of research.

Let us, then, before we go further, glance at those electric phenomena which underlie, and are applied to, the instrument we are studying.

2.—Fundamental Truths of Current Induction.

A long wire A B (Fig. 1) is placed in connection with a battery C and mercury cups D and D′. Another wire, A′ B′, is stretched close to the first wire, and placed in connection with a delicate galvanometer, G. It is known, by previous experiment, that a deflection of the galvanometer needle to the right would be produced by the insertion in the circuit A′ B′ G′ of a battery, sending a current in the direction of the arrow marked 1, and a deflection of the needle to the left by a current flowing in the direction of the arrow marked 2.

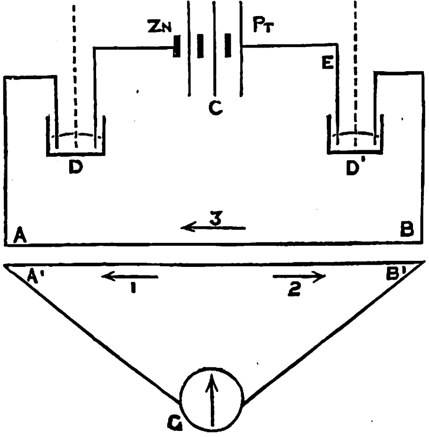
If the wire E is depressed until it touches the mercury, the circuit A B C (known as the primary circuit) is completed, and a current flows through it in the direction (by convention) of the arrow marked 3. At the instant of making contact with the mercury, the galvanometer needle swings to the left, showing that a current of electricity is flowing through the circuit A′ B′ G (known as the secondary circuit); and further, that that current is flowing in the direction of the arrow marked 2, and therefore in an opposite direction to the current in the primary. The galvanometer needle, however, does not continue in its position of deflection. It oscillates a few times and returns to zero. The secondary current, therefore, as the current flowing through the secondary circuit is called, is merely momentary.

If the wire E is removed from the mercury-cup the primary circuit is broken, the current ceases to flow, and at the same instant the needle swings to the right. A current, therefore, is flowing through the secondary circuit in the direction of the arrow marked 1, and consequently in the same direction as the current which has just ceased flowing in the primary. In this case also the galvanometer needle does not continue in its state of deflection, but falls quickly to zero. As before, the current is but momentary.

These currents flowing through the secondary wire are called induced currents, and the phenomenon induction.

If the primary circuit is again completed and, when the needle has come to rest, the wire A′ B′ is slowly moved away from the wire A B, the needle swings to the right, showing that a current is flowing through the secondary wire in the same direction as that in the primary. So long as the wire is being moved away the needle remains deflected. When the motion of the wire is stopped the needle falls to zero.

FIG. 1.



If the wire is moved back towards its original position the needle swings to the left, showing that a secondary current is flowing in an inverse direction to that of the primary. Here, again, so long as the motion of the wire continues, the needle remains deflected, but on the motion ceasing the needle falls to zero.

If the mercury cups D and D′ are joined by a wire, as shown by the dotted line F in the figure, the current flowing through the primary wire A B is decreased in strength. The needle swings to the right and then falls to zero, showing the passage of a momentary secondary current in the same direction as the primary.

If the wire is removed so as to restore the current to its original strength, the needle swings to the left and falls to zero. A momentary current in an inverse direction has flowed through the secondary circuit.

We may then enunciate the following laws:—

When a current begins to flow it induces in a conductor near it a current in a direction inverse to its own; when it ceases it induces a current in its own direction; and both these currents are but momentary.

When the distance between a conductor through which a current is passing and another conductor near it is decreased, a current flows through the latter in a direction opposite to that in the former; when the distance is increased, in the same direction as that in the former. These currents are not momentary, but continue so long as the distance is being varied.

When a current is increased in strength, a current flows through a neighbouring conductor in an inverse direction. When it is decreased in strength an induced current flows in the same direction as the inducing current. If the alteration in the strength of the inducing current is sudden, the induced current is momentary. If gradual, it continues so long as the strength of the inducing current continues to change.

To sum up: a current which begins, or which approaches, or which increases in strength, induces in a neighbouring conducting circuit a current in a direction opposite to its own; whilst a current which ceases, or which retires, or which decreases in strength, induces in a neighbouring conducting circuit a current in its own direction.

Alfred W. Soward.

PRACTICAL NOTES ON PLUMBING.—XXXI.*

By P. J. Davies, H.M.A.S.P., &c.

Seat-Action Closets (Fig. 173).

PERHAPS the best kind of water supply-valve for durability in a seat-action closet is that known as the double-*action* valve, *not double valve*, which means one that supplies a flush of water when first sitting down and a second one on rising. Such a closet and valve arrangement will be found illustrated in Figs. 173 and 174. The various parts are as follows:—A, 173, is the seat hinged to the back in such a manner that it will allow the front part A to drop about 1in. when anybody sits upon the seat; this slight depression communicates pressure to a plate under the seat and thence to the standard, B, which, in its turn, presses upon the end of the lever G, and so raises the weight F and the other end of the lever; this is connected by wire, rods, chain, pumpwork, or suchlike contrivances to the lever L, which allows the other end, N, to fall, and so pulls with it the chain O over the pulley Q, and actuates the sucker-valve U V, allowing the water to run for a given time, when the valve drops off and closes the aperture to the pipe W. Now, on rising from the seat the action is that the weight F again pushes up the seat, and as the weight falls, so will the lever G at I, and, by so doing, pull the wire J, bringing down the end of the lever L, and raising it at N, when it pulls up the loose chain S, and with it the sucker-valve, again allowing the water to flow to the w.c. for a given time. I should say that my friend, Mr. W. Ross, of Glasgow, designed this chain-action for after-flush valves; but I have adopted it for the purposes of a seat-action closet. K is a pull to be used for flushing the w.c. without rising from the seat.

FIG. 173.

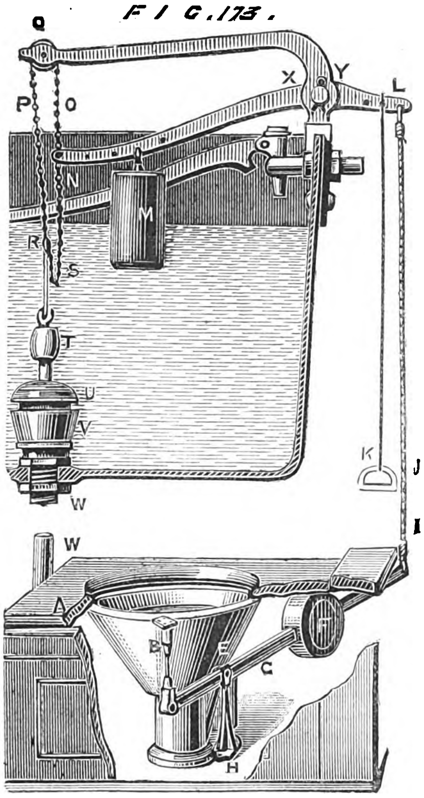


FIG. 173A.

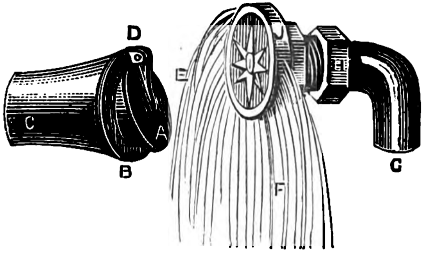
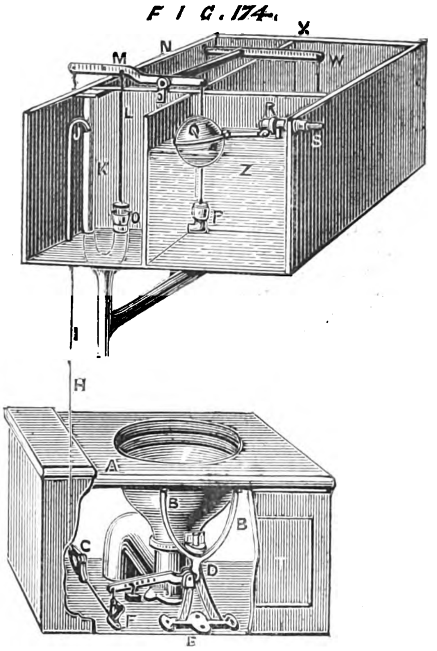


The seat of the closet represented in Fig. 174 has two horns or standards, B B, which are connected to the lever J; this lever is weighted at F, and by wire connected to the cranks, which communicate with the cistern-lever at M. It will be seen that if any person sits upon the seat, the lever M is immediately set in motion, and so first closes the valve O, by reason of this end of the lever dropping; but as the other end of the lever rises, after a little distance through last motion, so it brings up the valve P, and allows the water to fill up the compartment K, and so be ready by the time the seat is allowed to rise, freeing the lever M to rise likewise, and so opens the valve O, which flushes the closet. My readers will say that this is only single action; but by having the lever M connected to another, as at W X, the end N will fall with the end M, and first close a valve covering a pipe leading from either the first compartment L, or from another into W, when the valve on the N end of the lever is closed, so as to prevent the water entering from Z to W. The valve in the bottom of the compartment W allows the water to flush the w.c., which must take place when the seat is sat upon, and the valve O opens on the rising of the person from the closet-seat. So that this, like that represented in Fig. 173, can be arranged for either single or double action. I may also remind my readers that any of my double-action closet valves before described may be adapted to seat-action closets. Perhaps the better title for these valves would be, double-flush action valves.

FIG. 174.

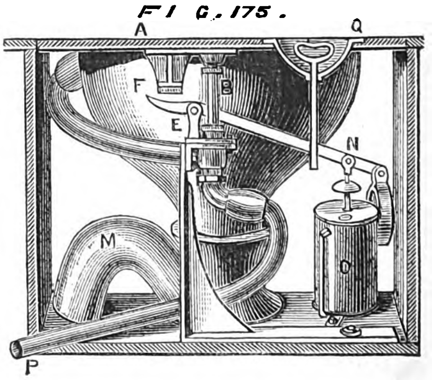


Under the Seat-Valve, Seat-Action Closets.

These closets are shown at Figs. 175, 176, 177, 178, and 179.

Fig. 175 is simply a stool-valve, having the end lengthened as at E, the seat being hinged at the back, as in Fig. 173. On sitting down

FIG. 175.



---

* From the *Building News*. All rights reserved.

upon the seat, the stud or spur F obtains an extra pressure upon the end of the lever, and brings up the other end N, and with it the valve B, and the stem of the regulator O, when the water runs continually unless it is fitted with a waste-preventing valve, as before described and illustrated at Figs. 149, 152, &c. Should this seat be fitted with a waste-preventing valve, it is often desirable to fit the dish and pull Q so that it may be used to flush during the time the closet is being used; but the handle must be of the slotted kind, to allow the lever to rise without the handle or pull. See M R, Fig. 177.

Fig. 176 is a seat-action valve somewhat similar to that described above, but is fixed upon the backboard V, or it may be fixed upon a strong riser (the board in front of a closet seat), or on a half-frame, as at Fig. 157 A. This valve is one that will continue running as long as the seat is occupied, but of course a waste-preventer may be used, in which case the dish and pull Q should be fixed, as in Fig. 175.

FIG. 176.

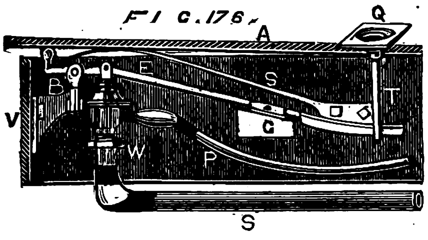


FIG. 177.

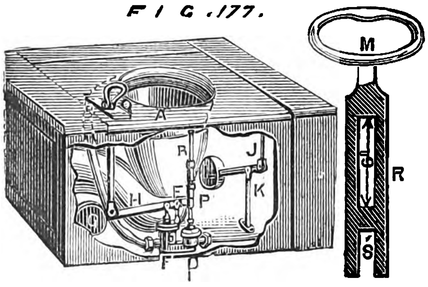
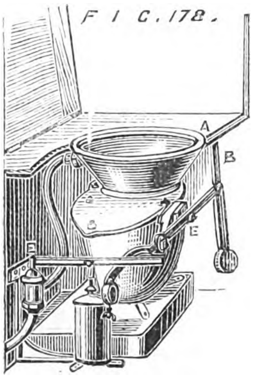


This is a seat-action valve, the seat of which, when pressed downwards, first shuts off the inlet-valve D, then opens F, but on rising from the seat, the valve D opens and the valve F slowly closes after a given time, so that to a certain extent this is a waste-preventer. The lever H should work through a slotted pull, as shown at R.M.S., so that the lever be allowed to rise, without the pushing up of the pull. This also refers to that shown at Figs. 175 and 176.

This is a seat-action pan closet; all that is required in this is the ordinary lever lengthened and the standard added, as at B; this is often fitted without thought. It is exceedingly bad, inasmuch as the copper pan remains open during the time that the closet is in use.

FIG. 178.



Comon's Valve Waste-Preventer.

Fig. 179 illustrates a waste-preventing seat-action closet. After what has been explained, the parts will be readily understood. On depressing the end of the lever F, it first closes the large valve leading from the air-chamber P to the basin (or the small valve from the supply-pipe); it next opens a small valve from the main supply, which allows the water under great pressure to enter the ball or air-chamber, when it compresses the air within, and, so to speak, becomes full. Now take the pressure off the end of the lever, and allow the small or inlet valve to close, and the large valve to open, the compressed air within the air-chamber will then force out all the water through the large valve and into the closet basin. This valve is very much used about the neighbourhood of Brighton.

(*To be continued.*)

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAI, AND LODGMENT.*

By John Watson Warman,

Associate of the College of Organists, London.

* Design Precise,

With reference to, and partly including, Key-Action.

(For Order and Posit see those Heads, at 91, *y*, and 92, *k*.)

c. We now come to a somewhat important portion of the Manual Design, and one about which there exists some diversity of opinion and practice,—viz., the exact arrangement and structure of the Manuals with reference to their Key Action; that is, speaking more minutely, the treatment of the Tails, Cranking, Sloping, and Crossing, of Keys and their Action, and the determination of some others points in connection with these. (For the *complete* Description of the Key and Coupling *Actions* the reader must of course wait till their own *Departments* are reached.)

d. In order to a better understanding of the subject, we will first consider, in the abstract, the several Points and difficulties which usually present themselves in the definite Lay-out of the Key-System. They are as follows:—

e. (1) *Removal of Key.*—It is obviously desirable that any Key of any Manual shall be easily removable at pleasure, while at the same time any increase in the number of the Key-Action *Centerings* is always to be as much as possible avoided. Thus; if the Key-Action (as is often the case with that of the Swell Section) do lead out straight horizontally from the Key Tail, it will as a rule be best to have the Nose of the Backfall or of the Square in actual contact with such Tail: by this means not only will the Removal of the Key be facilitated, and the Manual to Pedals Sticker perhaps shortened (see *rr*, next), but the cost of a set of Manual Stickers be saved. But, where the Key-Action leads perpendicularly down from the Key-tail, it becomes a question whether the additional cost, and friction, of a set of *Levers* shall be incurred, or whether the Tracker-End shall be attached *directly* to the Key-tail: the special circumstances and requirements of such particular case must then decide.

Note; that the said setting of the Square, &c., Noses in actual contact with their Keys will *not* facilitate the Removal of the latter, but will decidedly render such removal the more difficult, *unless* at the same time any *Stickers* of Action uniting such Keys to the *Pedals* be Wired *into* such Square or other Noses,—instead of into their Keys themselves. See here at *p*, next.

ee. One point to be always borne in mind is the *position* of the Manual. It is manifest, that for a Set of Keys which has a second such Set *beneath* it, there exists much greater necessity for the higher Keys' admitting of easy Removal,—for Access to the lower ones. See also (at *p* and *rr*, next) how this consideration is involved with that of the precise form of the *Coupler* Manuale to Pedals.

For an *Instance* see at 90, *m*.

f. (2) *Front Regulation.*—It is a matter of importance that the Key and Coupler Actions shall, so far as is possible, be adjustable at the Key *fronts*; that is to say, that a workman shall be able to regulate such Actions while he is placed at the Claviers themselves, and thus has the latter actually under his hand and vision. Otherwise the offices of a second person will become necessary for Regulating.

For *Instances* see at *d*, next; and again at 90, *m*. See also at 90, *h*, 9th parag. and on.

g. (3) *Key length Uniformity.*—It will be manifest that there must exist *some* particular dimension which is the best possible for the total length of a single Key (see 91, *n* and *nn*). This being so, it becomes theoretically desirable to have the Keys of *all* the Manuals made to such ascertained length; and such uniformity is as obviously more approached by making the *Tails* of every Manual to *overhang*—that is, to project beyond—the Tails of any Manual next beneath it. Among other Advantages of such a Treatment there is that of favouring the being able to easily secure more than one *Coupler* Manuale to Pedale with yet but one set of *Backfalls* for the same. Such a structure of these Couplers is sometimes very requisite,—see the *Tail-regulating* Variety of the *End-moving Sticker* Coupling-Action, in *Department* of latter. A *disadvantage* of such Tail Overhang will be indicated a little on (at *m*, next).

gg. See here in *Department* Coupling-Actions for a special *Instance* afforded in the *Leominster* Priory Church Organ.

h. (4) *Centering.*—There are three chief Considerations to be borne in mind in determining the point of posit for the Mid-Pin, forming the Centering of the Manual Key: these three are, (*a*) the requirements of the Action which runs from Key to Pallett, (*b*) the proper "balancing" of the Key itself, and (*c*) the suitability to the placing of a Coupler between two Manuals. Each must be looked at separately:—

i. As regards Consideration *a*, it is to be observed that there is or ought to be a fundamental Rule with all Organ Movements, that where "purchase" (leverage) has to be *gained* it should be gained as *soon* as possible, and where it has to be *lost* it should be lost as *late* as possible; the reason being the same in both cases, —viz., to avoid involving a larger amount of motion and of expenditure of material than is absolutely necessary. Thus, in the case of an ordinary Mechanical Stop Action it would be very unwise (though, by the way, our Builders do not seem to have yet properly realised this) to employ an *Equidistant* Centering for *all* its Squares, Levers, &c., *except* the one actually in *connection* with the *Slider*,—so making the Purchase to be obtained solely by such *Final* Square or Lever; for then, not only would the whole of the Stop-Action be made to move farther than there is any occasion for (and this might easily tend to a Fouling of the Square-Arms), but all the Arms except one would need to be longer, and the Final or other Lever would require to be wider, than would have been otherwise necessary,—the reason for this last being that the width of any Lever should manifestly be a ratio of the distance from its *Fulcrum* to its driving point farthest from latter, and not a ratio of the *total* Lever length. See on this matter fully in *Department* Stop-Action.

j. Now this Rule is of course, theoretically, just as binding with a Manual Key as with a Register Draw-Stop; but there are with the Key Action two further considerations which exercise, practically, a much modifying influence. The first of these is that as the Pallett ought to open as much as $\frac{3}{8}$ of an in. (see *Department* Wind-chest), and the Key-Touch is not pleasant if palpably over the same amount (see 93, *x*), there may not in fact exist any disproportioning *at all* in the Action from Manual to Pallett; the second is that, even if such disproportioning *should* be found necessary, the small amount total of the motion—certainly not over ½in., in all ordinary cases—very much reduces the chance of a Fouling, even without any attention to the said Rule. On the whole, therefore, it may be laid down that Consideration *a* should be, in the Key Action, held *subordinate* to the two points *b* and *c*.

---

* All rights reserved.

k. With reference to *b*, it will have been already apprehended—see 87, *k*—that (1) the Manual Key should be *slightly*, and *only* slightly, heavier forward than at its Tail, and that (2) it is *generally* advisable to endeavour to dispense with all Loadings (see 88, *e*). On the other hand, it is to be remembered that whenever a Key Action is really short, a little additional weight in the Key itself will be an aid in overcoming any "Pluck" existent in the Pallett (see again *Department* WINDCHEST). Excepting, therefore, when the Key-Action is tolerably long—say over 6ft. from Key-tail to Pallett-eye—, Consideration *b* may be regarded as not of great importance *unless* the Key-Tail is required to receive a Regulator for a Coupler (see *t*, ante), in which event care must be taken that the Loadings do not interfere with such Regulator. At this point see again at 88, *ee*.

l. Consideration *c* may be viewed as, on the whole, the most important of the three, because, as will be shortly seen (at *s*, next), the placing of a Coupler between two sets of Manual Keys is a Treatment often possessing very great advantages. Of course, the influence of any Coupler on the Posit of the Key Centering *ceases* at the instant that it is determined that such Coupler shall be *otherwise* located than in contact with such particular Manual (see *Depart.* COUPLING ACTIONS).

m. An *Instance* of the Center posit of a Manual interfering with a Coupler placed in contact with such Manual occurs in the Organ as Rebuilt some few years ago by *Hedgeland* (London) for the Parish Church of Hove, Brighton. In this case the Keys of both Manuals are not very long, and are Centered at points rather towards their Tails; the Tails of the Swell Manual extend so as to Overhang, by some little distance, the Tails of the Great Manual; and the [Swell] Coupler Contact-point is thus a like distance forward from the regular Action-point of the said Swell Key-tail: consequently, when the Great Manual Key is pressed down, it has a tendency, instead of raising merely the *Tail* of the Swell Key, to lift the *whole* of the latter; and the effect to the finger is very unpleasant. It will be obvious that a more *forward* posit of the *Centering* of the Swell Keys would have here lessened the disadvantage arising from the Upper Tails overhanging the Lower ones.

n. (5) *Key-Participation.*—It is of real importance (though the writer has not met with any instance of the recognition of this by any other Builder), when a Coupler which acts upon a Manual gives its impulse to a portion of the *Action* to Pallett instead of to the *Key* itself, that the latter be *engaged* with such portion of Action, and not be merely left free to *drop*: where this is neglected the Key has a tendency to *dance* during rapid or staccato playing on the Clavier *to* which such Key is united. The reason is simple: the attraction of gravitation takes a fraction of time to overcome the *vis inertiæ* of the Key, and this tardiness is increased by the fact of the Key's being only a *little* heavier forward (see *k*, ante); during very rapid passages the Key is both pressed and relinquished very swiftly, and so there is then a chance that any Key which is coupled to the Key pressed will be, during its descent, actually caught by the contact of its own Coupling Action. Besides this, in all cases where the Actuating Key is pressed swiftly down and then held, the Coupled Key, if unconfined by Participation, will tend to *rebound* up from the Bed-rail, and therefore to produce noise.

o. It has already (at *e*, ante) been seen that it is well to make the Nose of the Backfall or the Lever, or the Square to be in actual contact with the Key-tail; and wherever such Treatment is attained, and such Backfall, Lever, or Square is that upon which the Coupler acts, it will be very easy to secure the Participation of the Key, all necessary being to have the Tail of such Key suitably *Forked* (a Device of the present writer's), so as to receive the said Nose of such Backfall, Lever, or Square: and thus also the ready removal of the Coupled Key will not be interfered with. Another method of obtaining Key-Participation will be found given farther on (at *j*, next). Where a Sticker or a Tracker intervenes between the Key-tail of the Coupled Manual and the Backfall, Lever, or Square by means of which such Coupling is made, more difficulty will be experienced; and the case must be met by treating such Sticker or Tracker so that it fulfils the offices of both a Sticker *and* a Tracker. An *Exception* to the necessity for Coupling Key-Participation will be stated in proper place (at *q*, next; see also 90, *s*.)

It will now be obvious, that in deciding on the precise form of mechanism for any Coupling of a Manual, this matter of Participation should always be kept carefully in mind: see here what is said at *e*, ante; at *p* and *s*, next; and at 90, *r*. It is hereby necessary to add that the foregoing reasons calling for Participation can never exist in the Key *to* which the Coupling is made.

At this stage go over what is given at *m*, next.

oo. For the reason why it is not *always* desirable to secure the Participation by causing the Coupling impulse to be made upon the Key itself, see at *ee*, ante, and at *p* and *rr*, next.

p. (6) *Manuale to Pedals Coupler.*—It is to be borne in mind that a very *long* Manual Key, a very *short* Backfall (that under the Manual is here referred to), and an insufficient *Set-under* of Pedal-board (see 110, *i*) are all of them objectionable. One or other of the three is, however, often rendered *liable* by making the Sticker-head or other driving point of the Coupler Manual to Pedals to be in actual contact with the Key-tail so driven. The error can obviously be mitigated by the Treatment already enjoined for facilitating the Removal of the Key (see *e*, ante), and more definitely indicated in the preceding Head (at *o*, ante),—viz., that of making the driving point of the said Coupler to be against the Backfall, or Lever, or Square which is in connection with the Key-tail;—by which means the *Key* may be slightly shortened, or the *Backfall* under such Key a little lengthened, or the *Set-under* of the Pedals a little increased. All that is required is to so arrange the Coupling Backfall and Sticker that the latter enters and acts by means of a Piercing in the Nose of the Backfall, Lever, or Square that rests upon the Key-tail, instead of in and by means of a Piercing in latter itself. Do not forget that the necessity for Key Participation, just explained, holds theoretically good here just as strictly as in the Coupling of a Manual to a second Manual; and therefore the Nose of the Backfall, Lever, or Square should by rights act within a Tail-fork, as so described: but in practice an exception is—for a reason stated at *q*, next—sometimes allowed in respect of the Coupler *Great* Manual to Pedals; and such exception is the more to be tolerated because (1) the motion of the Manual Keys merely from their actuation by the Pedal Keys is not likely to be very rapid, and (2) because the Coupler Swell to Great will or may, in the case of such exception, be made to largely prevent the possibility of the Coupled Key's dancing (see *n*, ante; and 90, *s*).

(*To be continued*)

JUPITER.

By Prof. G. W. HOUGH, Director Dearborn Observatory.*

DURING the present opposition of Jupiter, the disc exhibits a variety of phenomena of interest to the practical astronomer.

Although this planet has received a good deal of attention during the past century, yet but few new *facts* have been added with regard to its physical aspect, since the time of Sir William Herschel.

It appears to be the generally-accepted idea that its surface is subject to sudden and extraordinary changes, sometimes accomplished in a few days or even a few hours. New belts are alleged to have been formed or to have disappeared in the course of an hour or two.

We believe conclusions of this kind have been too hastily drawn from the observations.

Owing to the rapid rotation of Jupiter, the various spots and markings follow each other so closely that one might readily imagine that what he saw was subject to change under his eye.

The great Red Spot, which has been an object of so much interest since 1879, becomes visible, in the Chicago telescope, at 2h. 25m. from the meridian of the planet, when its length is about one second of arc. As the rotation carries it further on the disc, it gradually increases in size, until, when on the meridian, it subtends an angle at opposition of 15 seconds. The smaller spots and markings, of course, become most conspicuous when near the meridian of the disc.

The visibility of objects depends very much, also, on the condition of the seeing. Sometimes the smaller spots are invisible for weeks, simply because the seeing is not good enough with limited optical power, and not because there has been any radical change on the surface of the planet. Its distance from the Earth is another important element in modifying the appearance of phenomena. After conjunction, the great Equatorial Belt and Red Spot are first seen and, as the Earth approaches nearer, other markings gradually appear, until the time of opposition, the greatest variety of phenomena is noticeable.

From September, 1879, when micrometer measurements were first begun, with the Chicago Refractor, on the markings of the disc, considerable change has taken place in its appearance at different times. But all changes, whether due to the distance of the planet from the earth, variable seeing, or other causes, have been slow and gradual.

The most noticeable change has taken place in belt No. 3 situated 6″ north of the equator. This belt, which was not conspicuous in 1879, gradually increased in width and distinctness in 1880, until at the present time its width is about 2·5″ of arc, and of the same colour as the equatorial belt—viz., reddish brown.

The equatorial region situated between the two outlines of the equatorial belt has been subject to considerable change, but the margins of the belt have not sensibly varied in width or latitude during the past three oppositions.

The great Red Spot, a conspicuous object even in a small telescope, is alleged to have materially changed in length during 1879, and again in 1880; but numerous micrometer measurements do not confirm this statement.

The following are the mean results, reduced to the mean distance.

	Length.	No. of Obs.	Breadth.	No. of Obs.	Latitude.	No. of Obs.
	″		″		″	
1879	12·25	9	3·46	8	– 6·95	8
1880	11·55	20	3·54	10	– 7·14	12
1881	11·50	8	3·40	3	– 7·41	7

These numbers indicate a small possible displacement of the centre in latitude, but it would be premature to assume such to be the case.

The colour of the spot is reddish-brown; however, when the seeing is unusually good, it appears almost a light pink.

The oval-shaped white spots, a number of which were observed in 1880, are quite numerous at the present time. They are about one second of arc in length, and are generally difficult objects to observe.

The following spots have been seen on belt No. 6. Latitude 9·5″ to 12·6″. They pass the meridian of Jupiter after the great Red Spot as follows:

h.	h.	h.	h.	h.	h.	h.	h.
+ 2.8	+ 3.0	+ 3.3	+ 4.0	+ 4.7	+ 5.2	+ 5.5	+ 5.8

There are also two white spots—more easily seen—near the great Red Spot, in latitude 9·63″ and longitude 0h. 36m. and + 0h. 24m.

The two White Spots situated in latitude 3·0″ south of the equator, which were observed in 1879 and 1880, were first seen this year on July 22nd. They appear to make a complete revolution around the planet in about forty-five days, corresponding to a rotation period of 9h. 50m. 9sec.

These spots, which are both occasionally seen at the same time, appear to be fixed relatively to each other.

The difference of longitude was measured with the micrometer as follows:—

1880.
July 24, + 23·5m.
Nov. 8, + 22·6m.
1881.
July 22, + 27·5m.
Nov. 26, + 27·5m.
Dec. 10, + 23·0m.

The fact that they have maintained for a year and a half the same relative position, and at the same time apparently drifted with a velocity of over 260 miles per hour, would seem to disprove the old theory that they are clouds floating in the atmosphere of the planet.

From observations made during the present opposition, it is probable that all the matter between the two margins of the equatorial belt, whether in the form of white spots or dark ones, moves with the same velocity—viz., a period of 9h. 50m. 9sec. And it is possible that the belt itself partakes of this motion.

---

* From *Science*.

The rotation period of the planet, deduced from our observations on the Red Spot, made in 1879 and 1880, was 9h. 55m. 33·2sec. + 0·09sec. $\sqrt{t}$, in which t is the number of days after Sept. 25, 1879, the observations during 1880 showing that the spot was retrograding with an accelerated velocity.

This formulæ is found to be essentially correct for the present opposition.

The "mean" period for Dec. 14, 1881, comprising an interval of 811 days, being 9h. 55m. 35·80sec. from observation, and 9h. 55m. 35·76sec. from the formulæ.

Assuming the rotation period as above, the centre of the spot has retrograded more than fifty degrees since Sept. 1879, not uniformly, but with an accelerated velocity. It seems difficult to account for this fact on any known hypothesis.

THE THEORY OF THE GAS-ENGINE.

At the meeting of the Institution of Civil Engineers held last week, a paper, by Mr. Dugald Clerk, was read, "On the Theory of the Gas-Engine." The practical problem of the conversion of heat into mechanical work had been partially solved by the steam-engine; but its efficiency was so low that it could not be considered as complete or final. Hot air in the past had been looked upon as a possible advance. Owing, however, to many futile attempts, it had long been deemed useless to look in that direction for better results. The great progress made in recent years with the gas-engine, from the state of an interesting but troublesome toy to a practical powerful rival of the steam-engine, had shown that air might, after all, be the chief motive power of the future. Three distinct types of gas-engines had been proposed:—

1. An engine drawing into the cylinder gas and air at atmospheric pressure for a portion of its stroke, cutting off communication with the outer atmosphere, and immediately igniting the mixture, the piston being pushed forward by the pressure of the ignited gases during the remainder of its stroke. The instroke discharged the products of combustion.

2. An engine in which a mixture of gas and air was drawn into a pump, and was discharged by the return stroke into a reservoir in a state of compression. From the reservoir the mixture entered a cylinder, being ignited as it entered, and without rise in pressure, but simply increased in volume, and following the piston as it moved forward, the return stroke discharged the products of combustion.

3. An engine in which a mixture of gas and air was compressed or introduced under compression into a cylinder, or space at the end of a cylinder, and then ignited while the volume remained constant and the pressure rose. Under this pressure the piston moved forward and the return stroke discharged the exhaust.

Types 1 and 3 were explosion-engines, the volume of the mixture remaining constant while the pressure increased. Type 2 was a gradual combustion-engine, in which the pressure was constant but the volume increased. Calculating the power to be obtained from each of these methods, supposing no loss of heat to the cylinder, it was found that an engine of type 1 using 100 heat units, would convert 21 units into mechanical work; in type 2, 36 units; and in type 3, 45 units. The great advantage of compression was clearly seen by the simple operation of compressing before heating, the last engine giving for the same expenditure of heat 2·1 times as much work as the first. In any gas-engine, compressing before ignition, igniting at constant volume and expanding to the same volume as before ignition, the possible duty D was determined by the atmospheric absolute temperature T^1, and the absolute temperature after compression, T; and it was $D = T - T^1 / T$, whatever might be the maximum temperature after ignition. Increasing the temperature of ignition increased the power of the engine, but did not cause the conversion of a greater portion of heat into work. That was, the possible duty of the engine was determined solely by the amount of compression before ignition. Compression made it possible to obtain from heated air a great amount of work with but a small movement of piston, the smaller volume giving greater pressures and thus rendering the power developed more mechanically available. Seeing the great difference produced between types 1 and 3 by the simple difference in the cycle operation when there was no loss of heat through the sides of the cylinder, the question arose, Which engine in actual practice, with the engine kept cold by water, would come nearest this theory? In which of the engines would there be the smaller loss of heat? Comparing the two engines, with equal movements of piston, it was found that the compression-engine had the advantage of a lower average temperature and a greater amount of work done; also of less surface exposed to flame, and consequently it lost less heat to the cylinder. Taking all the circumstances into consideration, it was certainly not over-estimating the advantage of the compression-engine to say, that it would, under practical conditions, give for a certain amount of heat three times the work it was possible to get from an engine using no compression.

It was interesting to calculate the amounts of gas required by the three types under the supposed conditions. Taking the amount of heat evolved by one cubic foot of average coal gas as equivalent to 505,000 foot-pounds, and calculating the gas required if all the heat were converted into work, it was found to be 3·92 cubic feet per h.p. per hour. Therefore, the amounts of gas required by the three types of engines would be:—

Type 1. $\frac{3\cdot92}{0\cdot21} = 18\cdot3$ cubic feet per H.P. per hour.
„ 2. $\frac{3\cdot92}{0\cdot36} = 10\cdot9$ „ „ „
„ 3. $\frac{3\cdot92}{0\cdot45} = 8\cdot6$ „ „ „

Comparing these figures with results obtained in practice from the three types of engine losing heat through the sides of the cylinder, it was ascertained that the amount of gas consumed was as follows:—

Type 1.	Lenoir,	95	cubic feet per	I.H.P.	per hour.
	Hugon,	85	„	„	„
„ 2.	Brayton,	50	„	„	„
„ 3.	Otto,	20	„	„	„

It would be seen that the order of consumption was what was required by theory. The Otto engine converted about 18 per cent. of the heat used by it into work, while the Hugon engine only converted 3·9 per cent. Taking the loss of heat to the cylinder as given by the comparison of the adiabatic line of fall of temperature with the actual line of fall as shown on the indicator diagram, it appeared much less than really was the case, as shown by the gas consumed by the engine. The maximum pressure produced was much less than would be expected from the amount of gas present; this was due to the limiting effect of chemical dissociation. The gas-engine presented a more complicated problem than a hot-air engine using air heated to the same degree. Analysing the disposal of 100 heat-units by Clerk's gas-engine, it was found to convert 17·8 into work, to discharge 29·3 with the exhaust gases, and to lose to the sides of the cylinder and piston 52·9 units. About one half of the whole heat used passed through the cylinder and heating-water. St. Claire Deville had shown that water was decomposed into its constituents at a comparatively low temperature, considerable decomposition taking place at 1,200° Centigrade. The cause of so near an approach to the line of theoretical fall, as was shown by the actual indicator diagram, was simply the continuous combination of the dissociated gases. At a maximum temperature of about 1,600° Centigrade, complete combination of the gases with oxygen was impossible, and could only take place when the temperature fell low enough.

In calculating the efficiency of the gas-engine from its diagram, all previous observers had fallen into error, through neglecting the effects of dissociation, and, accordingly, their results were much too high. To account for this so-called sustained pressure, Mr. Otto had advanced the theory that inflammation was not complete when the maximum pressure was attained at the beginning of the stroke, but that by a peculiar arrangement of strata he had made it gradual, and continued the spread of the flame while the piston moved forward. Mr. Otto called it slow combustion. This designation seemed to the author to be erroneous; such an action should rather be called slow inflammation. It existed in the Otto engine, but only when it was working badly, and was attended with great loss of heat and power. This was proved by a diagram, and by certain considerations deduced from Bunsen and Mallard's experiments on the rates of propagation of flame through combustible mixtures. The conclusion arrived at was that slow inflammation was to be avoided in the gas-engine, and that every effort should be made to secure complete inflammation at the beginning of the stroke. The author had found it possible to ignite a whole mass in any given time, between the limits of one-tenth and one-hundredth part of a second, by arranging the plan of ignition so that some mechanical disturbance by the entering flame was permitted. A diagram taken from the Otto and Langen free-piston engine, as given in a paper by Mr. F. W. Crossley, and an analysis of his reasoning, showed that the results were misinterpreted, and false conclusions arrived at concerning the nature of an explosion. Mr. Crossley considered that an explosion of gas and air, pure and simple, must be accompanied by a rapid rise and an almost instantaneous fall of pressure. This, he thought, was proved by the diagram, but in this statement the author could not concur.

From the considerations advanced in this paper, it would be seen that the cause of the comparative efficiency of the modern gas-engines over the old Lenoir and Hugon type was to be summed up in the one word "compression." Without compression before ignition an engine could not be produced giving power economically and with small bulk. The mixture used might be diluted, air might be introduced in front of gas and air, or an elaborate system of stratification might be adopted, but without compression no good effect would be produced. The gas-engine was, as yet, in its infancy, and many long years of work were necessary before it could rank with the steam-engine in capacity for all manner of uses. The time would come when factories, railways, and ships would be driven by gas-engines as efficient as any steam-engines, and much safer and more economical of fuel. The steam-engine converted so small an amount of the heat used by it into work that, although it was the glory and the honour of the first half of this century, it should be a standing reproach to engineers and scientists of the present time, having constantly before them the researches of Mayer and Joule.

ADHESION OF FLAT DRIVING-BELTS.

There are certain discrepancies in the theories of published experiments relating to flat driving-belts which recently drew from Mr. Robert Grimshaw the following remarks which we take from the *Journal* of the Franklin Institute.

The elements governing the adhesion of flat driving-belts to pulleys are pulley diameter, material and condition, and amount of crown; arc of contact, and belt material and condition, width and thickness, and tension. Each of these exerts an influence upon the adhesion; these influences being modified and in some cases neutralised, or even reversed, by the others. Of only one of them (arc of contact) it may be said that there are no apparent contradictions in its action. In his experiments Mr. Grimshaw used ten changes of pulley, ten of belts, three of arc, and about ten of tension. He employed pulleys of turned cast iron, wrought iron, and wood, and also the same pulleys covered with leather and rubber lagging; these pulleys having diameters of 18, 24, 30, and 36 inches. The belts used in testing were rubber, single and double leather oak tanned, waterproof and fulled, and wire centres; and canvass covered with composition. The arcs of contact were 90°, 180°, and 270°; and the tensions from 10 to 100 pounds per inch of belt width. The machine used for testing, and which was shown in part at the meeting, consisted of a strong wooden frame bearing a shaft 2 7-16 inches diameter, 5ft. long, upon which were hung the pulleys to be tested—both shaft and pulleys being held from turning.

At the meeting there were turned cast iron pulleys of 18in. and 36in. diameter, and a 26in. "taper sleeve" wooden pulley. The belt to be tested was placed centrally upon the desired pulley, and one end weighted with a given amount per inch of width. Force is applied at the other end until the belt slowly slips. The difference between the weights on each end represents the amount of friction of the belt upon the pulley, or the grip under the circumstances. The tension is applied by dead weights in a cage (the weight of the clamps and the cage being allowed for). The force to cause slipping is preferably applied by dead weights; but as in some cases this is considerably more than a ton, for convenience in such cases the force is applied by a lever of the second class, having its fulcrum under the centre of the shaft and its point of application of force to the belt in a vertical line tangent to the pulley at the point in the horizontal plane of the shaft. In other words, for each pulley the short arm of the lever was the same length as the radius of the pulley. The dynamometer, one of Fairbanks' standard traction machines, is first tested by hanging dead weights upon it, at each division at which it is to be used; and in testing the belts the mean of four readings is taken; although in many cases no readings are counted until there are three consecutive ones alike. As the result of over 900 tests and readings made, Mr. Grimshaw announced that the influence of increased pulley diameter is always to increase the drive; especially with light tensions. The influence of pulley material is so largely modified by the other conditions that no general rule can be laid down concerning it. The same is true of belt material. Increasing the belt width does not always increase the driving power, especially with thick belts, small pulleys, and light tensions. Increasing the belt thickness does not always increase the driving power, especially with small pulleys, wide belts, and light tensions. Increasing the arc of contact may be said to increase the drive in every case yet known. Increasing the tension increases the drive up to a certain point, beyond which, in many cases, no further increase of tension will cause any augmentation in the grip.

Replying to questions, Mr. Grimshaw said paper belts were but little used, by reason of their great stiffness and lack of elasticity; a certain degree of elasticity being a prime requisite of a belt in order to permit a difference in tension between the two sides by alternate elongation and contraction. As to leather or rubber, he said that in some situations, as for instance, in dry places, leather was the most durable; while for damp places rubber only would answer. Rubber was rapidly deteriorated by mineral oils and could not be used for quarter twist and crossed belts.

Replying to a question whether the tests as made were of any value in determining the driving power of belts at high speeds, he said that the conditions of friction were substantially the same, and that conditions varied, so that he could not give any reply to any question as to the relative driving power of different kinds of belts at high speeds, without all the conditions being stated.

Mr. Grimshaw said he had made about 200 tests of canvas belts under varying conditions with some substance to increase the adhesion, and that its tractive powers under the conditions of his tests were exceptionally good, while it was the strongest belt that he had ever broken. As to the objection that the mode of testing was hardly the right one, the tendency being, by adding weights to both ends of the belt, to break it, Mr. Grimshaw said that the friction between the belt and the pulley was the same as that between the pulley and the belt; that the driving power of any belt was measured by the difference between the tight and the loose sides, and that the pulley got all the difference in the tension; it could go nowhere else. As regards the danger of breaking the belts—the tension possible to put upon any belt was determined by the strength of the lacing or other fastening, and that for lacings the maximum safe strain, as laid down by Briggs and Towne, was 66⅔ pounds per inch wide; whereas single oak tanned leather belting broke at 1,000 pounds per inch of width. Hence the method of testing not only registered correctly both the light and the heavy tension, but the difference or grip, and did not induce artificial conditions. It had two certain practical conditions over attaching the dynamometer to the pulley rim. Attaching the dynamometer to the pulley rim allows only as much slip as the motion of the spring permits (about ⅛in. in the present case); while allowing the belt to slip gives a foot or two.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—VI.*

Lenses.

Of all the apparatus which the photographer uses, there is none of so great importance as the lens. With a bad camera shift can be made, and excellent work turned out, the only drawback being harder work and inconvenience for the operator; but with a bad or unsuitable lens nothing can be done. It will be necessary to define a few technical terms continually applied to lenses. By *depth of focus* is meant the power in a lens to represent sharply objects both near and far from the lens. The larger the aperture of the lens, the less the depth of focus. With every lens is supplied a set of *stops* or *diaphragms*. These are simply plates with holes of larger and smaller sizes in them, which are made to slip in front of or between the combinations of a lens. The more depth of focus is required, the smaller a stop must be used, and consequently the slower the lens will be.

By *width of angle* is meant the amount of picture which can be included. For example, with a camera placed in a certain position and pointed to a row of houses, one lens will include perhaps two houses, another four.

Distortion is a fault met with in photographic lenses. It causes straight lines near the sides of the object to be represented by curved lines in the image. *Flatness of field* is the quality in a lens of having the definition at the edge of the plate good, as well as that at the centre.

The *focus*—or, more strictly speaking, the *focal length*—of a lens is the distance between the lens and the ground-glass when the image is sharply focussed. In a single lens the measurement is taken from the centre of the lens. With compound lenses it is near enough to measure from the diaphragm to the ground glass.

The *aperture* in a lens is the diameter of the stop or diaphragm, or, where none is used, of the actual lenses. The rapidity does not require to be defined, but we propose to explain the factors which regulate it. Every lens is different in rapidity from others of another form, and each lens has a number of diaphragms varying its rapidity, so that at first sight it might appear a difficult task to put a value on the rapidity of a lens using any particular diaphragm. The law which governs the rapipity of lenses is, however, so very simple that its application is most easy, and we would try to impress on the beginner that he should thoroughly master it at the commencement of his practice. If he does so he will find the estimation of the necessary exposure a comparatively simple matter. In changing one stop for another, or one lens for another, he will have nothing to guess except the intensity of the light.

The method of comparing lenses is as follows:—State the ratios between the apertures of the lenses and the focal lengths of the lenses as fractions—the aperture as the numerator, the focal length as the denominator. Square the fractions thus obtained, and the resulting figures will give the ratios of the rapidity. It is usual to state the fractions thus: $\frac{f}{14}$ $\frac{f}{12}$ $\frac{f}{40}$ These fractions refer to lenses the first of which has an aperture one-fourth of the focal length, the second one-twelfth, and the third one-fortieth. We shall take a practical example. We are using a portrait-lens 10in. focus, and aperture 2½in.; that is, the focal length is four times the aperture, or we say the lens is working at $\frac{f}{4}$. The focal length, be it remembered, is the distance between the diaphragm and the ground glass. We now substitute a single lens of 12in. focus with a stop ¾in. in diameter. The aperture is now 1-14 of the focal length. The lens is working at $\frac{f}{14}$; square these two fractions, thus:—

$$(\tfrac{1}{4})^2 = \frac{1}{16} \quad \left(\frac{1}{16}\right)^2 = \frac{1}{256}.$$

The rapidity of the lenses is as 1-16 to 1-256. The exposure required will therefore be as 16 to 256, or as 1 to 16. Thus, if we had been giving two seconds with the portrait lens, we should have to give thirty-two seconds with the single lens. If the beginner will exercise himself in this rule for a little time, he will find that he soon gains wonderful facility in applying it, and he will find that it gives him a very great power in estimating the necessary length of exposure. With the same lens and different stops the rapidity varies as the square of the diameter of the stop, or as the area of the stop.

We shall now go rapidly over the different kinds of lenses most in use, giving the purposes for which each particular form is best adapted.

We have first the Single Lens (Fig. 1). It is the one with which we should recommend the beginner to provide himself, as it is the simplest form of lens, and is also the most generally useful. It is fairly rapid, has a fairly large angle, and gives wonderful definition and depth of focus. Its only drawback is that it gives slight distortion. If, for example, it be attempted to photograph a building of large size with it, the boundary lines will appear slightly curved, and the building will appear barrel-shaped.

FIG. 2

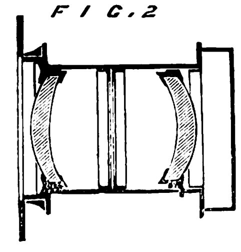

FIG. 1

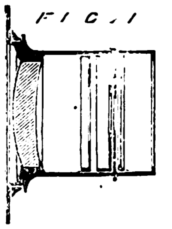

FIG. 3

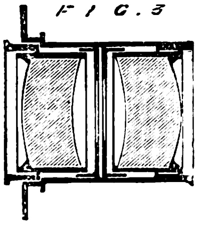

FIG. 4.

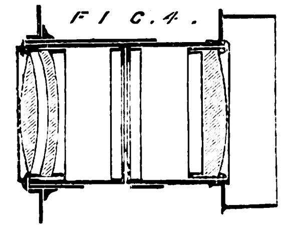

The Rapid Rectilinear or Rapid Symmetrical (Fig. 2) is one of the most useful lenses. It is very rapid, and one should be purchased when the photographer has so far advanced as to wish to attempt instantaneous effects. It gives no distortion, and about the same angle as the single lens.

The Symmetrical or Wide Angle Rectilinear (Fig. 3) is a slow lens, but takes in a wonderfully wide angle, so that it is useful for photograping objects when it is impossible to get the camera far enough away from them to use the rapid rectilinear. It is quite free from distortion.

The Portrait Lens (Fig. 4) is intended for portraiture pure and simple. The utmost ingenuity has been spent in the case of this lens to get the greatest possible rapidity, but many other good qualities have been sacrificed. Thus the field is round, the marginal definition bad, and there is very little depth of focus. For its own particular purpose it is, however, admirably adapted. With the very rapid plates which can now be had, it is quite possible to take portraits even in-doors with the rapid rectilinear or even the single lens, and we would not advise the beginner to purchase a portrait lens, at least, at first.

There are numerous photographic lenses sold under names different from any of the above, but all of them will be found to be very similar to one or other of the kinds described.

ODD WAYS OF MELTING IRON.*

There is probably as much reason for changes in the plan of melting iron as there is in moulding jobbing work. Melters will sometimes get nervous at being ordered to charge up their cupola in as many different ways as there are days in the week. A foreman that understands his business very seldom lays out a system, or a table of charges, for his melter to follow day after day in a regular jobbing-shop. The foreman may have various reasons for wanting his melter to make all these changes. To-day he may want the cupola to melt extra fast during the first of the heat, and slowly after some heavy casting is poured, in order to have melted iron to feed with. To-morrow, seeing that some moulder will not get ready in season, this order may be reversed. As he does not want to keep his men late when it can be avoided, he orders the cupola charged, so that the men having small work can be pouring off while the large casting is being got ready. This casting, that, perhaps, weighs five tons, may not be thick in any of its parts, so as to require much feeding, and the bottom can be dropped soon after it is poured. In this way the only moulders kept late are the ones that were going to keep the whole shop's crew behind, which, for a shop that pays overtime, would be expensive, and in any case, is not pleasant for the men.

On some days the shop-floor may be covered with a class of work that is better for being poured with dull iron, and the next day the work may be such as to require very hot iron. Again, there will be heavy and light castings, requiring entirely different grades of iron; and to complicate matters the foreman, if an observing man, will see that the brand of iron is not of the same grade as the last car-load. All of the above causes, to which could be added quality of fuel, sometimes make a thoughtful foreman think of a string tied full of knots.

I will try and show in this, two of the many plans that may be adopted to meet different conditions that may be new to some. One is for melting special grades of iron, and the other to retain the bed in a cupola after melting a heat for a break-down job, or for a piece of casting that is wanted in a hurry.

I worked once in a rolling mill company's foundry, and sometimes when everything was about poured off, there could in the distance be seen some one of the managers running towards the foundry, as if he meant business. Our ignorance of the cause of his haste would soon be enlightened by seeing a team, or some men bringing a pattern. This pattern would be given to some competent moulder, and two or three reliable moulders would be retained to help him. By this time all the moulds are poured off and the cupola man has received instruction not to drop the bottom, but to prepare it to melt iron again in the course of three or four hours. The way to do this is as follows: Leave the blast on until you are sure all the iron in the cupola is melted, and instead of dropping the bottom knock out the front breast, and with a bent hook pull out all the clinkering coke or coal and iron cinder that can be felt or seen. Then fill up the breast-hole with loose sand, and every 5 or 10 minutes take away the sand and pull out again whatever clinkers or iron cinders will have formed, repeating the operation for the first half-hour or so, until you are sure that all the droppings of iron and clinkers are pulled out. After this, every half-hour or so will be sufficiently often to clean the bottom out. The stopping up of the breast every time the clinkers are cleared out is done to prevent the fuel from burning away, and also to keep the clinkers and droppings of iron from being chilled with the air.

After the cupola is well cleaned out, there should be some fuel shovelled in, so as to freshen up and keep the fire in good burning condition. When the moulders have their mould or moulds about ready, then make up the breast as usual, and shovel in the fuel for a bed, the same height as for a regular heat. After it gets to burning, charge up the iron wanted, put on the blast, and you will soon have your cupola melting iron again. The first two or three hundred of iron is generally dull, and sometimes will have to be poured into a pig-bed. After this the iron will come hot enough for ordinary casting.

---

* Condensed from the *Photographic News.*

* By Thos. D. West, in the *American Machinist.*

The question of how large a heat a cupola run in this way would melt could not be better answered than by the following: One morning early, two or three men were called upon to mould up a piece of machinery for a repair job. The melters and helpers were called to the shop to get the cupola ready as soon as possible. The casting, the weight of which was about 2,500 pounds, was poured about eleven o'clock in the morning. The iron was all blown down, the breast knocked out, and the cupola treated as above described, until the time for the regular afternoon heats, which were never less than 12 tons. The blast was again put on, and after the first few hundred pounds, the iron was as good and as hot as usual. The time that the cupola was held from one heat to another was about four hours. The size of this cupola was a five-foot shell.

To prevent the mixing of different grades of iron, when melted at one heat, has been the cause of a deal of thought and many experiments with foundrymen. I know of a foundry owner who makes a practice of melting only one grade of iron at a time. If he has a roll to cast, he will only charge up the iron weighed off for it. The blast will then be put on and all the iron in the cupola melted and tapped out. The blast is then stopped and the bed renewed with coke. Another grade of iron is then charged up and all melted down. I remember one day his making three distinct blow-outs during the same heat. The first was about 7,000 pounds for a roll; the second, about 2,000 for soft work, and the third was common iron to finish off a heat of about eight tons. The size of the cupola that this was done in was about a 4ft. 6in. shell. This same gentleman has a reputation for turning out castings of the grade of iron wanted, and it is owing to no more nor less than the way he charges up his cupola, and in being particular in the mixing and selection of his iron. The objection to this style of melting is that there is a little more coke used, and it takes from half an hour to one hour longer to run a heat off.

It seems almost an impossibility to run a straight heat, when there are two or three different grades of iron to melt, without having them mix more or less, and the less the weights of the different grades to be melted the more will they be liable to mix. For example: Charge an ordinary cupola with a regular charge of a special grade of iron, with the usual charge of fuel on top, and so on, charging with distinct grades of iron. As the grades of iron melt, pour some castings, the weight of which should not be less than 50 pounds. On the following day melt the special grades of iron by themselves, and pour some castings, and then compare the runners and gates, and you will see that there is a difference.

It is generally known that hard iron will melt sooner than soft iron, and most foundrymen, when making a casting of hard iron, have the hard iron charged first, to make sure of having the casting of good, sound iron and of the grade wanted. If they have soft iron to run, it is generally charged on the top of the hard iron. This is a plan that I do not always approve of, as there are always more or less particles of any grades or charges of iron left remaining among the fuel and on the bottom and sides of a cupola, and which will affect two or three other charges.

A plan that I find to work well, when there are two charges of soft iron wanted, is to melt the hard iron first; then, instead of putting the soft iron directly on the top of the hard iron, I charge about two charges of common iron—either soft or hard. On top of these charges the soft iron will be charged. After, as I think, all the hard iron is down, then the common is tapped out until, by the number of ladles carried off, I think it is all melted. At this point the soft castings are poured according to the degree of softness wanted. The softest casting wanted, if there have been three charges of soft iron charged, should be taken from what is thought to be the middle or second charge.

In some cases where I have only a small amount of very soft iron wanted, I charge up the soft iron on the top of the bed, which should be burning well, and should not have in as much fuel by from 4in. to 6in. as for ordinary heats. This iron will be put in from one half-hour to one hour before any of the other charges of iron are put in, and when all is ready to have the rest of the charges put in, make the first charge of fuel (that which is placed between the first and second charges of iron) a large one; as much larger than usual as the bed was left low. By this means the large charge of fuel takes a longer time to get hot enough to melt the upper charge of iron, and when the first charge of iron is melted, the second, or large charge of fuel, will come down and raise the bed up to the proper height to run the balance of the heat off. I have by this plan charged hard iron on the top of soft iron.

When not taking out the soft iron too closely to the amount charged up, the castings have been as soft as if the hard iron had never been charged up. It is in having only small quantities of different grades of iron to melt, that there is serious trouble with their mixing together. With large quantities there is more chance of having castings the grade wanted, but even then the melter must use judgment in seeing that the iron is charged as it should be, and the foremman should be watchful, so as to know that the iron is taken away from the cupola as the grades melt or come down. There is nothing about a foundry that requires such changes in its management as a jobbing foundry cupola.

SCIENTIFIC NEWS.

COMET *a* 1882 (Wells) was seen on the 6th by Mr. J. Rand Capron, in a position between Lyra and Draco. Mr. Coulcher, of Downham, Norfolk, writes that he has observed it on several nights since the 3rd with a 10in. mirror, and also with a 4in. achromatic. Writing on the 11th, he says it is now about 16° from Vega in a line towards the Pole-star. The *Science Observer* for March 24th gives the elements and ephemerides already telegraphed to Lord Crawford, and says, "it is an exceedingly pretty comet, and can be seen with a telescope of 4in. aperture." Prof. Lewis Boss says that the comet is remarkable for its small perihelion distance and its intense brightness. Some of the observations, we learn, were made under considerable difficulty, in consequence of fogs and clouds. Only ten comets have been known to approach the sun as closely as the present visitor to our heavens; but according to the American observers, the inhabitants of the southern hemisphere will have the best view, as, after passing through Cepheus, it will appear to make an abrupt turn in May towards the sun.

Mr. Christie, the Astronomer Royal, has been admitted a member of the Clockmakers' Company, in accordance with custom. At one time, the Government gave premiums for the best chronometers, but these are now made so accurate that a sufficient number are obtained without the incentive of a prize. The Clockmakers' Company, however, still give prizes, and the award is made by the Astronomer Royal in his official capacity.

The flint disc for the great Lick telescope is now on its way to Alvan Clark and Son's works to be fashioned into a lens. It weighs 374lb., is 38¼in. in diameter, and over 21½in. thick. The melting and pouring occupied four days, and thirty days were allowed for cooling. The disc of crown-glass is also cast, and is now nearly cooled. Each disc cost about £2,000, M. Feil having a practical monopoly of this branch of glass-making.

The Gresham Lectures on Astronomy will be delivered by the Rev. E. Ledger at Gresham College on April 18, 19, 20, and 21; those on Physic by Dr. Symes Thompson on April 25, 26, 27, and 28; those on Geometry by Dean Cowie on May 2, 3, 4, and 5; those on Divinity by Dean Burgon on May 9, 10, 11, and 12; those on Rhetoric (Mr. J. E. Nixon) on May 15, 16, 17, and 19; those on Law by Dr. Abdy on May 23, 24, 25, and 26; and those on Music by Dr. H. Wylde on May 30, 31, June 1 and 2.

Mr. J. Baillie Hamilton's new harmonium was used in Westminster Abbey last week, when Dr. Bridge's oratorio of "Mount Moriah" was performed. Opinions seem to differ as to its merits.

The Shipwrights' International Competitive Exhibition will be opened in Fishmongers' Hall on May 2, the prizes being open to all nations. Mr. ex-Sheriff Burt offers a prize of £50 for the best system proposed for the improved ventilation of passenger vessels.

Swan's lamps of five candle-power, with a portable battery of five bichromate cells, are recommended to photographers for work in the dark room, and also when using ether.

Mr. Clement E. Stretton sends us a copy of his pamphlet on railway accidents, the second edition, price 1s., published by Spencer Bros. and Russell, Leicester. We need scarcely say that it is a clear and unbiased account of the brake question as it concerns railway accidents, and in a few days it will be issued with an appendix containing the letter published on p. 109 of our last number, and five sheets of diagrams, two of the Westinghouse brake, two of Sykes's signalling and interlocking arrangements, and the brake efficiency diagram.

We have received the first number of the *Journal* of the Postal Microscopical Society (1, Cambridge-place, Bath), a quarterly published at 1s. It makes a good start with several interesting papers, and five pages of lithographed plates, some coloured.

The report of the sun's behaviour during the last quarter of 1881, by M. Tacchini, shows a continuous falling off in the mean daily number of protuberances, from a maximum in September. The increase of solar activity, however, is shown by the number of protuberances being nearly double that of the fourth quarter in 1880; their height and extent have increased very little. They figure in all the zones (as in the second and third quarters), and the greatest number are outside the zones of the spots. The spots and faculæ present, as in preceding quarters, two maxima between ± 10° and ± 30°, and the faculæ extend to higher latitudes than the spots. The frequency of spots is always greater in the northern hemisphere.

The disappearance of the sardine on the French coast during the last two years (a real disaster for the population of La Vendée) has been attributed by M. Blavier to a supposed displacement of the Gulf Stream, due to an exceptional ice-block in Davis Straits obstructing the polar current, whose encounter with the Gulf Stream is the cause of its bending towards the French coasts. In this connection, M. Broch has called attention to the variations observed, from time to time, in the herring fishery on the Norwegian coast (chiefly carried on between Capes Lindesnaes and Stadt), a record of which has been carefully made at Bergen for some centuries. Since 1870, the herring has failed on the south-west coast; and since 1874, even in the northern region; but during the last two winters, a few bands have visited the island of Karmö. It appears to be made out that it is the greater or less distance from the coast of the region where the herring finds its food in summer and autumn (consisting of myriads of small molluscs, crustaceans, &c. forming banks and tingeing the water), that determines whether the fish will come to this coast to milt. In his three years' exploration of the North Atlantic, Prof. Sars observed those banks of animalcules were being displaced eastward, and the recent reappearance at Karmö seems connected with this. The displacement of those banks of herring-food, now east, now west, is doubtless due to variations in winds and ocean currents, and the investigation of these latter is important both economically and zoologically.

Invention has been active of late years in the matter of fire-damp indicators, and a new apparatus by a Belgian, M. Body, is now to be added to the list. It is very simple, not requiring long and minute manipulation, like the Forbes apparatus, nor electric bells like M. Monniers. It consists of a Carcel lamp, the flame of which is protected, as in the Davy lamp, by wire gauze; the wick, chemically prepared in a way not yet made known, breaks whenever the proportions of fire-damp in the air exceeds 1-23. The rupture of this wick, which is distinct from the illuminating wick, releases the detent of an alarm-clock, which then acts. The apparatus, placed at either end of a gallery, thus indicates near danger, and its source and direction.

An interesting memoir on German railway carriages was lately read by Herr Wichart at a meeting of railway engineers in Berlin. There there are four principal types in use. The first have in each compartment six seats, with separate arms and back; the second, four sofas for eight persons; the third, two wooden seats for ten passengers; while the fourth have no seats. It appears that the average of seats (or places) occupied is 11·7 per cent. in the first, 23·2 in the second, 22·3 in the third, and 30 in the fourth. Herr Wichert would do away with the second class, and make the 3rd more comfortable. At the end of 1879 there were some 2,655 carriages in Germany lit with gas on the Pintsch system. At the end of 1880, in Prussia alone, there were 3,732 gas-lit carriages, while 1,487 were having the system applied. Herr Wichert affirms that the cost is not greater than with ordinary oil, and the illumination is twice as good. In the first years of railways on the Continent, the Prussian carriages were not lit at all, and in 1844 the king called the attention of the companies to this defect, which was only supplied two years later. To-day, Germany may boast (the author says) of having the best-lit carriages in the world.

It is a familiar fact that the glass discs of Holtz machines become rapidly inactive; and, for remedy, the disc is coated with an insulating varnish, or inclosed in a glass cover and surrounded with petroleum vapour, and so on. Prof. Marangoni has lately hit upon a device, which he thinks superior to others. In his Treatise on Electricity, Jenkin says that a glass-rod, which, because of surface-conductivity, is not a good insulator, will acquire this quality if immersed 24 hours in distilled water, and allowed to dry for the same time without being rubbed with anything. Prof. Marangoni treated the turning discs of his Holtz machines thus, and found that they immediately recovered their maximum activity. True, the activity decreases, but the same thing happens with varnished discs. Hence, it is easier and less expensive to have recourse to the distilled water.

The absolute tenacity and conducting power of phosphor-bronze wire have of late been thoroughly investigated by the German Telegraph authorities, who have, from the outset, favoured the use of this wire for their extensive aërial telephone lines. The results of the inquiry (given in the *Electrotechn. Zeitsch.*) are adverse to the wire, and the authorities have resolved meanwhile not to make larger use of it.

The French Government has viewed favourably a proposal made by M. Nicole, to erect, over the ruins of the Palace of St. Cloud, a Crystal Palace similar to that at Sydenham.

The Böttcher telephone (described in the German *Journal of Applied Electricity*) is chiefly distinguished by the fact that the magnet is not, as in other systems, fixedly connected with the case, but by means of screws and steel wires is freely suspended in it. Thus the magnet can, within certain limits, oscillate with the membrane, but in opposite direction. When the membrane is attracted there is mutual approach; in the other case mutual separation. Thus the difference of approach and separation is considerably greater than in ordinary telephones, and there is a stronger inductive action. A bent speaking-tube is fixed over the orifice of the instrument. The receiving telephone has also some distinctive features.

It has been recently noticed by M. de Chardonnet, that a very sensitive galvanometer in a telephone circuit is not affected by the sound of a tuning-fork, pipe, or the voice, so long as the sound continues of the same intensity; but variations of the intensity cause deflection, and in opposite directions, according as it is an increase or a decrease. The effect is most marked when the transmitter is affected by a short sound, as a detonation or a body lightly striking the plate. M. de Chardonnet gives (*Comptes Rendus*) a simple explanation of hese effects.

The cables of suspension-bridges are generally formed, it is known, of parallel metallic wires, bound at intervals by wire ligatures, and equally strained in manufacture. Whatever the care taken, however, it is always found that there is about 18 to 20 per cent. of the wires whose work is nil. M. Arnodin has conceived the idea of twisting the cables like ordinary cords. There is a two-fold advantage in this. First, the resistance of a twisted cable is superior to that of an untwisted one of the same composition, by 10 or 11 per cent. This is proved by recent experiment at Lyons. Secondly, the interior vacua are reduced to a minimum, and if the cable be plunged in a semi-liquid mixture which returns to the solid, or, at least, pasty state, at ordinary temperature, its form will keep this matter in the vacua, when the temperature of summer would tend to make it flow out, and the introduction of water is prevented. Further, while oxidation may occur, this, being chiefly on the under surface, will injure the twisted cable less (the wires being alternately above and below) than where the injury is localised to a certain number of wires always the same.

It is estimated that the average cost of furnishing motors, magneto-machines, regulators of lenticular apparatus, and the cost of installation in connection with M. Allard's scheme for transforming 42 lighthouses on the French Coast, will be about 25,000 francs per lighthouse, or 5,250,000 francs in all. A sum of 1,750,000 francs will further be necessary for amelioration of certain lighthouses, and special difficulties of depositing apparatus in lighthouses on isolated rocks. Lastly, the establishment of 80 wind-signals, at 50,000 francs a lighthouse, will cost about 1,000,000 francs. The grand total is about eight million francs. For annual maintenance, about 7,000 francs more will be required for each lighthouse than on the oil system (total 300,000 francs).

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

COMET WELLS.

[19912.]—THIS object was found here in the 6in. Cooke equatorial, with comet eyepiece, on Thursday night (the 6th), just before the moon rose. The position was between Lyra and Draco, and nearly that given in Earl Crawford's circular, No. 50 (R. A. 18h. 28m. 53s., D.N. 44° 43′, Berlin midnight). Tail straight, short, and *n p.*; small condensed nucleus, about equal to 7th mag. star; object rather faint, as the sky was light.

J. Rand Capron.

Guildown Observatory, April 8th.

[19913.]—A SUPPLEMENTARY number of the "A. N.," published this morning, contains an ephemeris of Wells's comet, furnished by two independent observers. The paths, as given by them, agree so closely, that either of them will probably serve for picking up the stranger before it becomes visible to the naked eye; yet the elements which those gentlemen adopt differ very considerably. For instance, one calculator adopts

T = 1882, June 8·43114, and log. q 8·639526,

the other,

T = 1882, June 16·6130, and log. q 9 07186.

A third computer, in the same supplement, who, however, gives no ephemeris, adopts

T = 1882, June 28·3886, and log. q 9·10111.

The distances, too, of this comet, both from the Earth and the Sun, differ very materially as given in the two ephemerides spoken of; perhaps, therefore, it is not out of the way to hope the columns of the ENGLISH MECHANIC may shortly contain an article by the trustworthy pen of "F.R.A.S.," setting forth the future behaviour of the comet in question, which, *ut aliqui volunt,* promises, towards the end of May, to become a specially grand object, attaining, indeed, on the 8th of June, a brightness 5,824 greater than it had on its discovery on the 19th of March, thus enabling it, at the end of May and the first days of June, to be observed advantageously during the daytime.

Chelsea, 10th April. **M. W. Laing.**

STAR MAGNITUDES—VARIABLE STAR η URSÆ MAJORIS.

[19914.]—I HAVE very much pleasure in informing "Opera-glass" (letter 19861, p. 80) how I attempted determining the magnitudes of the stars in Ursa Minor and Draco. I assumed α Ursæ Minoris as 2·4, and from it γ of the same constellation was rated as 3·5. β Ursæ Minoris was excluded as variable. The stars 5 Ursæ Minoris, and 4 Ursæ Minoris were rated at 4·5 and 5 0. We thus have:—

α Ursæ Min.	2·4
γ ,,	3·5
5 ,,	4·5
4 ,,	5 0

The usual limit of magnitude for my opera-glass is 7·5; 24 Ursæ Minoris was rated 6·0.

Of course the accuracy of all subsequent determinations depends on the standards. For determining standards, the judgment can alone be used, and if backed by some little experience, the results will never differ half a magnitude from the truth, I believe. I cannot give the stars Mr. Read chooses for standards; one, I know, was γ Ursæ Minoris, over which we differed half a magnitude, and neither of us could convince ourselves which was wrong. Singularly enough, the stars rated from γ Ursæ Minoris by both of us, agreed quite well together. Mr. Read, I believe, next determined the magnitudes of a second lot of stars, and used this second series, together with his first standards, for determining the magnitudes of a third set of stars. For my own part, I preferred referring each new star back to my original standards, and usually did so, but occasionally checked the result by comparison with stars, not standards, whose magnitudes I had already determined. In a word, my method is (1) to assume certain magnitudes for certain stars, and call these standard stars; (2) to determine from the standard stars a series of intermediatory magnitudes; (3) to compare each new star with the standards, and to check the result, sometimes with the intermediatory stars.

I think your correspondent will see that great accuracy may be thus obtained. If the standards are carefully chosen, I cannot imagine a greater error than 0·2 between any determinations on different evenings. The star A is of the 4th mag., and star B of the 4½ magnitude. It is quite easy to assign to star C, which is less than A, but brighter than B, a magnitude which cannot be 0·2 from the truth. Mr. Read's method should insure greater accuracy, as he would use some star D as intermediatory star, and assign a magnitude from A and D if the star was brighter than D, or B and D if the star was fainter than D. Your correspondent will understand that I am speaking all this time about observations made with an opera-glass. In using the opera-glass the stars must be put out of focus, and we then have discs of light to compare instead of points; at the same time the effect of colour on the eye is in a great measure eliminated. It is quite easy, with a little practice, to move from your standard stars on to the one you are observing without altering the focus. This should be done so many times as to leave no doubt in the observer's mind as to the relative brightness of the star compared with his standards. The comparisons can be made with great rapidity after a little practice. The determination of magnitudes of small stars in the opera-glass, like small stars in the telescope, is hopeless, and for all accurate purposes the range of an opera-glass, I think, should end at a magnitude at least above the *minimum visible.* For my own part, I like to confine my observation to the region round my standards. As I only do star sequencing at intervals, I have several sets of standards, which I am hoping now to compare *inter se.* I believe, however, that the differences will affect the sequences throughout, and thus allow a correction. I give here the stars which accidentally occur in two of my sequences. The first was in February, 1879; the second about the same date in 1881, or two years later. The occurrence of the same stars in both sequences was quite accidental, and the standards of comparison were different:—

	Seq. VI. A.	Seq. XXII. B.	Diff. A – B.
30 Geminorum..	4 9	4·6	– 0·3
15 Monocerotis..	5 2	4·7	– 0 5
13 ,, ..	5 1	4·9	– 0 2
8 ,, ..	4·9	4·5	– 0·4
δ^1 Canis Minoris	5·9	5·7	– 0·2
ρ ,, ..	5·8	5·5	– 0 3
14 ,, ..	6·0	5 9	– 0·1

The sign is the same throughout, and hence it is quite fair to apply a correction, making use of a correction to B of + 0·2. We shall then be able to compare the real differences between the determinations of magnitude. We shall thus have:—

	Seq. A.	Seq. B.	Diff. A – B.
30 Geminorum..	4 9	4·8	– 0·1
15 Monocerotis..	5·2	4·9	– 0 3
13 ,, ..	5·1	5·1	– 0·0
8 ,, ..	4·9	4 7	– 0·2
δ^1 Canis Minoris	5·9	5·9	– 0·0
ρ ,, ..	5 8	5·7	– 0·1
14 ,, ..	6·0	6·1	+ 0·1

Excluding 15 Monocerotis, which is variable, there is only one star where there is a difference of 0 2 in magnitude.

I feel sure that any of your correspondents who have time at their disposal, if they try this method, will agree with me that a very correct magnitude may be obtained with an opera-glass.

I am very pleased to see that Mr. Gemmill has found traces of a period of five days in η Ursæ Majoris. The period I obtained for it was:

d. h. m.
P. = 4 17 36

but this did not represent the observations very satisfactorily. I have been waiting for this object to be well placed for observation, and then hope to try again. **T. E. Espin.**

Wallasey Rectory, Birkenhead.

THE LUNAR SNOW-LINE.

[19915.]—SINCE letter 19463, p. 302, I have been away in the Singphu country east of Asam, on one of my periodic searches for a route hence to China, and I now see "F.R.A.S." refers to that letter at p. 351, Dec. 16.

I was pretty close to the snow on Dapha Boom, but the elevation is only 15,000ft. At the same time I am aware that had I been able to carry out the experiment he refers to, the little square of black velvet laid on the snow in sunshine would have sunk in, while the white calico square would have remained on the surface.

Snow being white (and not black), I cannot see how this bears on the question, or demonstrates the impossibility of its existence on the moon's surface. When I registered a temperature of 172° F. in the sun at 300ft. above sea-level, I took it for granted that the *same rays* at some 30,000ft. above me would not have melted snow; and in this I am, I think right; and hence we can, and do, have perpetual snow under a vertical sun in the Tropics (even with a *comparatively* dense atmosphere). Why, therefore, not on the moon, where there is practically no atmosphere?

Sibsagar, Asam. **S. E. Peal.**

WATCH-REPAIRING.

[19916.]—MANY thanks to F. C. Putley. If you wait with a little patience you will, no doubt, see why I "cram the art, &c." My instructions for putting in a new pinion are genuine, and may be easily done by any amateur. I admit that Fig. 27 and Fig. 28 are not just what I wanted them to be, but as I shall eventually treat this subject again, I must ask you to wait. I want the amateur to have a little practice before we go into art properly. Why don't you read instructions as well as look at my drawings, and, if you don't believe it, just make some turns according to my instructions? You will be surprised that so simple an arrangement can turn out such a good job.

You must excuse me if I say you are mistaken if you think I ever recommend an amateur to *scrape* a hairspring, I said *draw* it. Did you ever draw one? I presume you never have, therefore, you you don't know anything about it; practice is one thing, theory is another. If a hairspring is properly drawn, it is the best way to weaken it. I shall give full instructions for drawing hairsprings in a week or so. I recommend the bouchon for the potence slip, but it won't do as a rule for any other part of a *verge* watch. It may be freely used in a Geneva, or small pivot watches, unless the hole is much worn, in which case it is useless; the holes in verge watches generally wear oblong, or egg-shaped, and it is necessary that the hole should be put in the same place that it originally occupied. My method does not mean repitching: it simply means that the new hole shall occupy the same position that the old hole did before it became worn out of shape, and it is as simple as A, B, C.

You must have been a very unfortunate being. I have let Geneva watches run down ever since I have been in the trade, and I have never had any accident. Do you think there is sufficient power in the spring to pull off an escape-wheel pivot? Do you mean a French horizontal timepiece? I have known these to act in that way, but only very common ones. You are bound to let down spring in lever watches—you have no option. I will simply suggest, "Live and learn." You will have plenty of chances to criticise when I begin "extra repairs." **A Fellow-Workman.**

[19917.]—IT is much more easy to find fault with the good work of others than to do the good work ourselves. Mr. F. C. Putley condemns "A Fellow-Workman," but why does he not do better work himself? I have asked a number of questions through the "E.M.," and the only answers I have got worth a penny are those of "A Fellow-Workman."

"Amateurs" may be considered those who, through some fault or other, have not been permitted to learn their trade correctly, yet have a considerable knowledge of a good deal connected with it. Those who know nothing of the trade whatever, and require to be told how to take a watch or clock to pieces, would do well to leave the trade alone. A voluminous article is extremely undesirable, as the young workman neither has the time nor the patience to go through it. French bouchons are very undesirable in repairing a wide hole, and to rebush and repitch is the only proper way to do it. Some tell us to use punches to repair holes with, which advice I trust no workman will ever take. In my opinion, "A Fellow-Workman" is by far the most able horological correspondent connected with the "E.M." **Guyot.**

THE TIN-POT BATTERY.

[19918.]—HAVING called Mr. Bennett's attention to the letters of "W. W. H. G." and J. H. Anderson in your last issue, I am authorised by him to state that, in the course of his experiments, he tried both the modifications of his battery to which these gentlemen refer.

As regards the first, the porous cell, or an equivalent partition, can only be dispensed with when a weak and inconstant current is required. The sacrifice of strength and constancy by the omission of such a partition is most marked. "W. W. H. G.'s" cell would only ring his bell for 1½ hour without rest. A properly-constructed tin-pot cell would ring it more powerfully for five or six weeks without stopping.

In respect to the second, Mr. Anderson will find after a time that, owing to a local action between the can and the granulated carbon, the iron will become rusted, and ultimately eaten through. This result is not difficult to understand, it being a case of two conductors of different potentials in contact in the same solution.

John McWhirter.

The National Electric Company (Limited),
Glasgow, April 10th.

DYNAMO-MACHINES AND GALVANIC BATTERIES.

[19919.]—I FEAR "Conrad" (19882, p. 81), will produce more wrath in those who make a machine on his plan, than the machine itself will produce current. He really appears to be under some very serious misapprehensions as to the actions which go on in these machines. Certainly he is in error as to the action of the Brush machine, and also as to his views of what he calls well-known laws. He appears to have mixed up the actions upon the wires, and those upon the cores. In the Brush machine the principal agency is the increase and decrease of magnetism in the core; direct action upon the wire is scarcely employed. As a consequence, it is at the moment when the iron projections, in passing the field magnets, take up the strongest magnetism into that arc of the armature which lies between the north or south poles of the field magnets (which are not, as he seems to think, those which face each other), and again when they leave those poles, that the strongest currents are produced. That is to say, they are produced almost entirely by gain and loss of magnetism, together with a smaller amount due to what De Moncel calls the polar introversion, which occurs in the various parts of the iron.

In his own design I fear he will find he has done the things he ought not to have done, and left undone the things he ought to have done; he simply increases and decreases magnetism in his core, thus generating an alternating current. But the best way of decreasing N. magnetism is to convert it to S. magnetism, which gives a current in same direction. As to the heating of the core, I think it will be found just the same as if the magnetism were reversed—less powerfully, of course, but only proportionally so to the less effective result produced.

The secret of getting current out of magnetism is to make the greatest changes possible, and to put the conductor in circuit just when the greatest change occurs. "Conrad's" plan fails in both; he minimises the changes, and by connecting only opposite bobbins, and it appears only putting in circuit the pair which have most and least magnetism, he carefully escapes utilising the change of magnetism, which occurs not at those points, but in the whole revolution while the bobbin is slowly gaining and slowly losing magnetism.

It is doubtful whether "W. H. G." (19903, p. 107) has made any improvement upon Mr. Bennett's soda-battery by substituting crushed carbon for iron; but, whether or not, he has done nothing new. In fact, the only point of Mr. Bennett's battery is its simplicity and cheapness of construction and the use of iron borings. The soda-cell was well-known before, and has been patented probably several times. With iron borings the negative element may be an old can, though I think the tin would be dissolved off and transferred to the zinc. But if carbon is packed in a tin can, it will be advisable for the cell to be stood in a saucer, as it will not be very long that the liquid will remain in it, for it will soon be eaten into holes.

I do not know where caustic soda is to be had at the price named, which is about the retail price of soda crystals, which will not act; but it is easy enough to procure a solution by boiling them with caustic lime—not in a tinned saucepan. The chief defect of the soda cells is that the air which must have access soon destroys the caustic soda and converts it to carbonate. **Sigma.**

SCIENTIFIC RESEARCH AND THE ROYAL SOCIETY.

[19920.]—WILL you allow me to call your attention to a somewhat notable fact in present scientific doings? You know that some years ago, through some extraordinary and benign influence, the then Government of the day were induced to grant *out of the public funds* the sum of £4,000 for the particular and express purpose of aiding the cause of "scientific research." This sum was confided to the Royal Society as the most fitting body to select those whom it might think most worthy of help, and who, in the ranks of the "outsiders," as the late Astronomer Royal phrased it, were thought to have in any way merited or earned some public recognition and help.

You will recollect that it was in your journal that I first called the attention of astronomers to the fact of the impossibility of really utilising the many and costly observations of the Transit of Venus, while the difficulty of the "Black-drop," as it is called, was still unaccounted for, and its true cause, at least, but partially known. It has always been contended by astronomers—and is so still, I believe—that it is solely owing to some occult influence exerted by the planet on the light which comes from the sun as it nears and passes the ;planet, thus preventing the clear *outlines* of the *planet* and the *sun* from being seen to touch each other *sharply* and *clearly* with well-defined outlines.

It is thought generally, I believe, and certainly by the Royal Society, that *light*, in passing by the outline or edge of any body is, by the influence of such body, *deflected* or *inflected*, or both together, and so *bent* (or split) out of its closest and straightest path; and thus, when it reaches the eye-retina, must needs make a confused, or *shaded*, or undefined outline. I cannot but think, on the contrary, that this singular appearance is owing solely to the *size* or linear dimensions of the source of the light, whether of the sun or the flame of a rushlight.

Sir, at the last Transit, as you will remember, many thousands of pounds were expended, not here alone, but all over Europe, in the observations of the Transit, and that the *result* was simply *nil*. I must contend that the same failure *must* needs occur at the next and coming Transit if the same course of action be pursued, and the above facts be passed by without another examination and analysis. As a subject of scientific research, I must contend that it is well worthy of note and further inquiry, and I have petitioned the Royal Society to give it a passing thought, and a little help or aid out of the fund at their disposal. I have suggested a new *eye-piece* to the Transit telescope, which I feel sure would, at least, much lessen, if not eliminate, the difficulty, and have asked for help to do this. I have also endeavoured to show that the words *inflection*, *deflection*, *irradiation*, are consequently obsolete, and without definite meaning here.

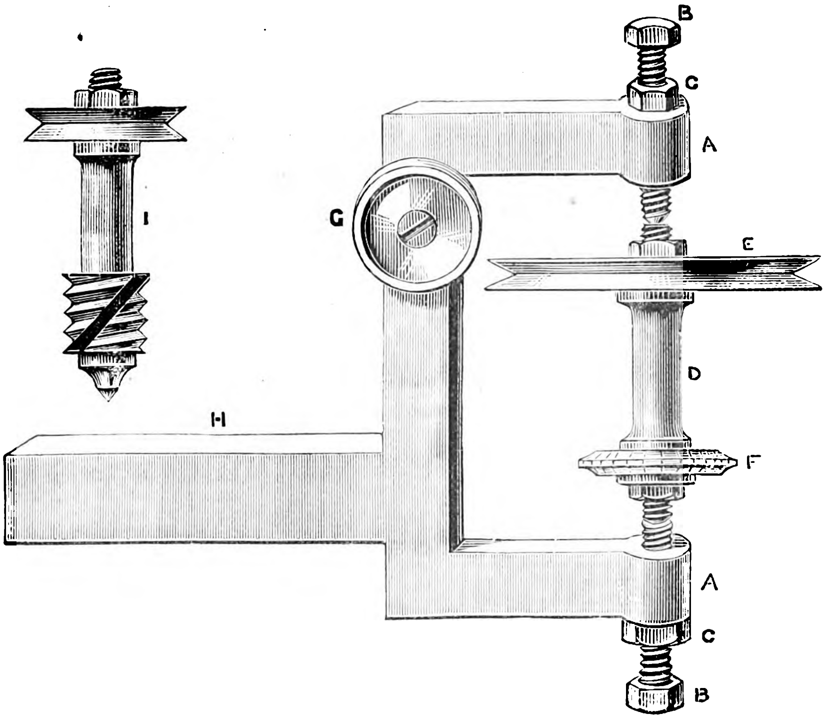
My sole object in asking you to insert this note is to induce the Royal Society, with whom the matter wholly rests, to institute a further inquiry into the difficulties and perplexities of this curious subject, and thus to, in time, admit it into the category of objects of scientific research; and, in the end, to make the coming observations of the Transit of Venus more certain of true results than the last.

Would it not be as well, I would venture to ask, in the future, to *divide* this large sum granted for scientific research, giving a portion to *each* one of the leading scientific societies—e g., the Astronomical—thus to deal more carefully, and in detail, with the separate items of the fund?

C. Bruce Allen.

WHEEL-CUTTING FRAME.

[19921.]—I AM now about to describe a simple, but very efficient, tool for cutting the teeth in such brass wheels as an amateur is likely to require. The illustrations given in books, Northcott for instance, of wheel-cutting frames describe them as requiring two slides, a vertical and horizontal, worked by leading screws, and capable of being swivelled round at any angle, the cutters also being driven by a spur-wheel and pinion. These are of course very elaborate and costly tools; but the one I am now describing will, I can vouch from experience, do the work equally well, though perhaps it will not cut a heavy gear as fast, with the exception of spiral wheels which I have never had occasion to cut, and for which the frame requires to be set at an angle, and to have a traversing motion independent of the slide-rest. In making this tool, of course it will have to be proportioned to suit its own slide-rest. The frame is of wrought iron, and any handy smith can make it. The two bosses A A are tapped with a $\frac{3}{8}$th screw, and in doing this I had to use a special tap with a long plain shank turned down to the size of the bottom of the thread at the small end; this was passed through one boss, and the point of it entered the hole in the other, which it just fitted, before the tapped part commenced to cut, and when one hole was tapped it was changed to the other one in the same way, so that both holes were of necessity tapped in the same line. It may be possible with great care to tap the holes true with a set of ordinary taps; but I have made myself a set of three taps of different sizes of this pattern for tapping opposite holes, and I can never make a mistake with them. B B are two steel screws with the points hardened; the upper one has a male centre and the lower a female one, between which the spindle runs, having contrary centres to correspond. The reason of this is that they may better retain the oil when in the upright position, than if both screw-points were male. C C are two lock-nuts which keep the screws from getting loose while in use. The spindle D is also of steel, with its ends hardened. F is a gear-cutter which is secured by a nut, and which can readily be taken off and exchanged for another, of any shape or size required; these cutters can be bought at all tool-shops, and always have the same sized holes through them. E is a brass-grooved pulley of 2½in. diameter, which I have found amply large for any work that I have done, and is keyed on to the spindle and secured by a nut; the spindle must be made long enough to allow E to clear the top of the wheel which is being cut. G is one of a pair of grooved pulleys which guide the gut band to the overhead, after passing round E. The axles of these pulleys I have made pretty long, so that they may take up their own position, according as there is a larger or smaller pulley on the spindle. H is the shank which is secured in tool-holder of rest, and should be packed up to the proper height, so that the centre of cutter F may be in a line with the lathe-centre. The teeth of the wheel to be cut are, of course, spaced by division-plate of lathe, and the cutter, while revolving horizontally, is fed up to its cut and traversed by slide-rest. In a similar manner, with a properly-shaped cutter on spindle, taps and reamers can be fluted, but when working on steel the cutters must be kept well lubricated.



I is a hob for cutting worm-wheels, such as are used on eccentric or oval chucks. It has a pulley at one end which may be smaller than the one on the other spindle; at the other end is cut a screw of the same pitch as the tangent screw which is to work in the wheel; this has flutes similar to a tap, but cut spirally instead of longitudinally, and the object of this is that as only two or three threads touch the wheel at a time, the spiral groove gives it a better lead than a straight one. Most authorities tell you, when cutting a worm-wheel, to first partly cut out the teeth, one by one, with a single-point tool in a fly-cutter, spacing them with the division-plate, and afterwards finish them with a hob. But my plan is as follows, and it succeeds admirably. Chuck the wheel to be cut on a mandrel between centres, and turn a semicircular groove in it, the diameter of your tangent-screw at the bottom of its thread; then put the index point into the first hole of your division-plate, and with a point-tool in the slide-rest make a mark at the bottom of semicircular groove; then take an outside screw-tool of the same pitch as tangent screw, and placing the first point of it in the mark just made, and the other points in a line with the groove, give it a slight tap of a hammer. This will mark three or four dots; then with the point-tool still in the slide-rest, try if the space between the dots will correspond with any even divisor on the division-plate; if it does, then the teeth of the wheel will come out even also, but if spaces do not come out even, then you must turn a little more off the wheel, and try again. When I have got the spaces right, I take a small cold chisel with the corners rounded off, and with a slight tap of a hammer make a transverse indentation at each dot; three or four are enough. I then take off the carrier from the mandrel, so as to allow it to revolve freely between centres, and with the worm-cutter in the frame fastened in the slide-rest, I bring it up so as to engage in the first of the indentations on the wheel. These indentations give the cutter a grip so as to start it; and on driving it from the overhead, the wheel at once commences to revolve, and the hob to cut the teeth out; and by keeping it pressed up to its work, the teeth are finished in a very few minutes. Sometimes, when it is not necessary to have a close fit between the worm and wheel, and when there is considerable strain on it—as, for instance, the wheel which drives a rose-cutting frame at the end of stem—I make the wheel a narrow spur, with teeth the ordinary shape, and the worm can then be cut very deep.

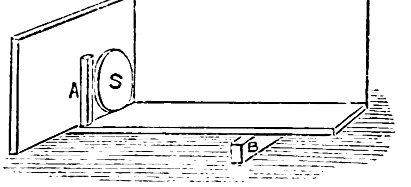
F. W. G.

GRINDING AND POLISHING GLASS SPECULA.

[19922.]—To understand the mode of testing specula that I have found the most convenient, the amateur must bear in mind what I explained to him in my last letter (p. 57), that the focus of the outside rays of an ellipse parabola or hyperbola is longer than the focus of the inside rays when tested at the centre of curvature. Now, we can have various ellipses and various hyperbolas, but we can have only one parabola, so we have only to calculate how much longer the outside rays, or the rays from any other zone, are than the inside rays of a parabola, the diameter and focus of our speculum to be tested, and then measure the actual lengths of the foci of the corresponding outside, or any other zone, of our speculum, and we at once can see what figure it is. Thus, if the outside zone rays are not so long as for a parabola by calculation, then we know we have an ellipse, as to what eccentricity it is immaterial to us, for we want only the parabola. If they are longer than the inside rays ever so little, then the figure is an ellipse only just removed from the sphere, and what we have to do is to make them still longer, till they correspond with the required proportion; then we have the parabola. On the other hand, if the outside rays are longer than the calculated proportion, then we know we have the hyperbola, and we must shorten them, or lengthen the inside rays, till we get the required proportion, when again we have the parabola. We must first know, therefore, by what rule to calculate the foci of the various zones. Now, there was a discussion in our columns some time ago on this point, and a difference of opinion seemed to exist; in fact, the rule I use is, I believe, different to Dr. Draper's. I hope our mathematical friends will now come forward and give us the aid of their skill in this direction. Surely there are readers who can settle it once for all for us. I cannot help thinking there is the will to help others as much in our mathematical friends as is exhibited in our mechanical friends. I will now tell them the rule I have found to give results that correspond as near as we can measure with the actual testings on a celestial object as to coincidence of the foci of the various zones. It may not be mathematically correct, but I believe it is very near. It is as follows:—Divide the square of the semidiameter of the zone by double the focal length for parallel rays; or, in other words, the radius of curvature (so called). The amateur will observe that this rule gives four times the aberration as the spherical aberration for parallel rays (see p. 57, sec. col.). I hope our mathematical friends will be on the look out for any error in our mathematics at all times, as we shall be glad to be corrected into the truth; and to have to own at any time that we have been mistaken is only to say, in other words (I wish we could always feel so when set right), that we are wiser now than we were before. While studying the above rule, the thought at once occurred to me that, Could I devise for the amateur sufficiently accurate and easily-constructed means to measure the proportion existing among the foci of the various zones, I should give him what he could use at once without waiting till he got the experience of a With or a Calver, for all he would have to do would be to see that the shade came on exactly the same on each side of the zone he was measuring, and he would have its exact focus, as I was careful to dilate upon in my last letter as being the first lesson he had to learn, so that he need not go beyond his first lesson in the Foucault's testing to apply this form of the test. Now, one great advantage of this mode of testing is that it gives the exact figure, for it is easy to see when we have experimentally determined the various focal lengths of the various zones, whether the figure is a regular one or not, and this by simply comparing these lengths with the calculated lengths for the parabola, and thus this mode of testing becomes a fearful tell-tale.

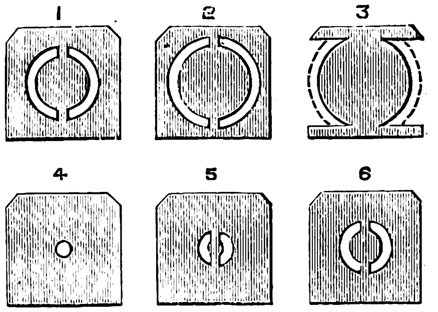
I will now proceed to describe as briefly as possible, consistent with what I consider necessary, to enable the amateur to make the apparatus and carry out the testings, and I hope if any amateur has any difficulty, either in making or understanding the description, he will communicate with me direct, and I will either communicate with him direct or give the explanation in some future letter in our columns, as my object is to make the thing plain once for all. It would be interesting and instructive to those who happen to have by them the communication of our old correspondent Mr. Tydeman, to read his description of the Foucaults test; it is in Vol. XIII., p. 464. He will then see that we have made some advance since then, when he compares it with the way I am about to give him. Fig. 1 is what I call the speculum trough. It is made of three pieces of board. I should advise the amateur to make it out of 11in. broad board, then it will do for testing a 12in. or 15in. speculum, should he go on to that size. Each piece may be from 18in. to 24in. long, ¾in. thick will be sufficient; they need not even be planed. S is the speculum in position, with a strip of wood, A, not quite so thick as the speculum, tacked on to the back board, to prevent the speculum from rolling out by accident; B is a piece of wood, to move backwards or forwards, and thus to throw the image of the hole in the chimney higher or lower, and thus make it level with the hole; now, by moving the right-hand end of the trough from him or towards him, the amateur can put the image of the hole just on the edge of the shutter.

FIG. 1



The amateur must now make six stops out of ordinary cardboard, as represented in Fig. 2. They should be made out of pieces about 6¼in. square (for our supposed 6in. speculum), so that they may fully cover the face of the speculum; but the centres from which the circles that form the zonal openings are struck should be just as high as the centre of the speculum; thus the stop will project about ⅛in. on each side of the speculum, and about ¼in. above it; the top corners are cut off, so that I can feel which side is to be placed top when leaned against the speculum. No. 3 is a circle 5in. diameter, with the bottom of the square left on to support the 5in. circle over the centre of the speculum when placed against it, thus leaving the outer zone ½in. wide; the top of the square is left on also, so that the left-hand side of the zone shall be exactly like the right-hand side in symmetry; for I find that to compare two areas of light as to the amount of light, which is the important thing here, I must have the two areas equal and symmetrical in shape. I have represented the edge of the speculum by dotted lines; the other figures will speak for themselves. I need only observe that the circles are for No. 2, 4in. diam.; No. 1, 3in. diam.; No. 6, 2in. diam.; No. 5, 1in. diam.; No. 4 is a simple hole 1in. diam. As to this last stop, I now never use it, for it is impossible to tell with sufficient accuracy how the shadings come on with so small a circle; but I thought it well for the amateur to try for himself, so that he may get the experience; but besides, this centre is always covered by the shadow of the small mirror. To calculate the foci of the zones, which are all ½in. wide, I take as the diameter of the zones a middle line on each; thus the outer zone middle line would be 5·5in. dia.. the half of this 2·75, the square of this 7·56. Divide this by the radius of curvature, which in our supposed case of 60in. focus would be 120, therefore the dividend would be ·063—*i.e.*, the focus of the outside zone would be for a parabolical figure ·063in. longer than the centre ray of stop No. 6, and so on for all the other zones, which would be as follows:—

FIG. 2.



No. of stop	1	2	3	4	5	6
Dia. of zone	5½	4½	3½	2½	1½	0
Aberration	·063	·042	·025	·013	·005	0

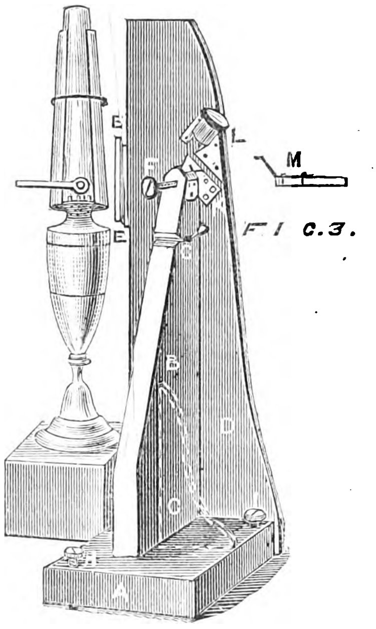


FIG. 3.

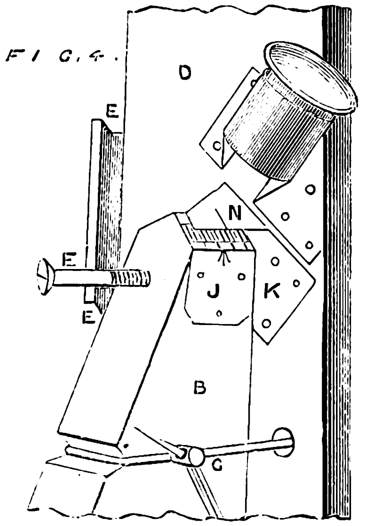

FIG. 4.

Now for the measuring apparatus and lamp. These are represented in Fig. 3. A is a piece of wood, the side A 6in., the other side 8in. In my case it is 1¼in. thick, but this was because that was the thickness of the piece of wood I used up for this purpose, but 1in. thick will be enough. B in mine is about 1½in. thick. but 1in. will do, especially if there be a bracket C (marked in dotted lines); but using thick and hard wood I needed no bracket. I should advise the amateur to put a bracket in any case. B is screwed firmly to A from the underside of A. D is wood from ½ to ¾ thick, hinged to A at D's lower end by two small hinges put as far apart as possible. These hinges ought to have no shake, even when opened and shut singly, and then they will not allow the piece D to twist when used together, and as far apart as possible. E E is the shutter tacked on to the back of D. This shutter is made of sheet-zinc, with the edge bevelled and made straight and smooth. It is 4in. long, is bent as shown in this Fig. and in section in Fig. 2, p. 57. It projects from the edge of D about 1¼in., as shown in section at M. F is a screw—in my case an ordinary wood-screw, with all round the head notched with small nicks, to act as a milled head. I could have made this and all the other screws and metal in brass, and finished it all as well as a mathematical-instrument maker could, even to the varnishing; but I have purposely adopted the simplest means, so that the amateur may not be discouraged, but feel that he can make all that is required; and to help others, we must put ourselves under the same conditions, with all their disadvantages, then we can properly feel for others, and help them, with our skill, to get over their difficulties and disadvantages. Well, D is kept against the point of the screw F, by the elastic-band G; all this is shown on a larger scale in Fig. 4. I must warn the amateur that this screw F must be made to turn very easily with the thumb and finger, as, in fact, the other two screws, H and I, must. H is a ¼in. ordinary Whitworth screw, with a six-square head; but this may be a wood screw—an objection to a wood-screw is that its thread is rather coarse; but, still the amateur may not despair if he has to use one. I have let in a nut on the under-side of A, and made H to fit loose through the wood. This screw is to adjust the shutter exactly to the focus of the outer zone, when the index near to F is set to ·063 to start with; therefore we will call it the adjusting-screw, for it is evident that when screwed down it will lift up the end of A, and throw back the shutter E E away from the speculum and *vice versâ*, so that we can set the shutter exactly to any place in the cone of rays to commence our measurements from. Of course the rough adjustment is done by pulling or pushing the whole affair along the table or bench that it rests on, being careful to keep the shutter not far from opposite the centre of the chimney, and about 1½in. from the hole, as I explain at p. 57 in former letter. The lamp will sometimes have to be moved to keep the proper relationship between it and the shutter. I is another screw like H, and its effect will be to move the shutter at right-angles to the movement produced by H, so that the effect of screwing I down will be to pass the shutter from left to right across the cone of rays. Now, as we can screw down I very gently, we can watch the shadings on the speculum with the greatest ease and comfort, stop it at any point, bring it back by unscrewing I, and then pass it over again, and thus study the indications over and over again, till we have thoroughly mastered the lesson or satisfied ourselves as to what we are seeking to find out. This screw I call the shutter screw, because it is to shut off the light by moving the shutter across the cone of rays, and thus produce the shadings we have to judge from; this screw is an immense comfort, as compared with the square of our friend Mr. Tydeman of 10 years ago, as likewise is the screw, H; but it was the old square of our friend that led me to the improved idea, and I only hope my improvement will lead someone else, it may be 10 years hence, to a still further improvement; the fact is, we are all dependent on those who have gone before us, and our legitimate boasting is often very little compared with our actual boasting; the fact being a large mind never boasts, but ever feels that the ocean of knowledge is still before him. But to return to our description. At the corner of A, behind B and C, there is a stud on the under side, projecting about ¼in., which rests on the table and keeps A above it, so that there are three points on which the whole affair rests—viz., the stud, the adjusting-screw, and the shutter-screw: it rocks, therefore, on the stud in two directions at right angles to one another by means of the two screws, which screws, by the way, ought to have rounded points, but only just removed from the flat; in this respect the ¼in. screws are better than the wood screws, although by putting a bit of metal under each of the points of the wood screws, these would do as well as the ¼in. The measuring part at the top of B is represented on a larger scale in Fig. 4 (the same letters refer to the same parts as in Fig. 3). J is a piece of sheet-zinc having divisions to the 100in. tacked on to the top of B and bent as shown, for the projecting part N of the sheet-zinc K to slide over, with one line as shown for the index near to N. The part K is extended on D at the back of B, so that the point of the measuring-screw F shall push against it, and not against the bare wood. L is a piece of sheet-zinc, bent as shown, to hold an ordinary watch-maker's eyeglass directly over the index N and the divided part of J, the eyeglass being carried with the index N, both being on D. It is always right for reading off the position of the index on the divided part of J; any lens will do that is about 1 or 1½in. focus, placed at the bottom of L, and at such distance from N as to see it distinctly. The divisions on J are long division every 10th in., short division every 100th in., with each 5th or middle division a little longer than the 100th divisions. The amateur can easily divide this for himself if he can borrow a straight edge or rule divided into 100ths. The middle long division on J has an arrow to it, as shown, to indicate 0, or the starting-point to reckon from. The single line on N ought to be at the end of the division furthest from D. When the measuring-screw is drawn back so as to allow D to be pulled against B by the elastic band G. The division on J need not be more than 4-10ths. The amateur, if he cannot get a rule divided to 100ths, can get his zinc divided at any rule-maker, or, I should think, any mathematical instrument maker. Mr. Lancaster, for instance, would, I have no doubt, get it done for him if he would send the piece of zinc by post, but he must mark with ink or any other way that will not scratch the surface, where he wants the divisions to be put; the single line N he can put himself, after he has bevelled or thinned down the edge; he has only to put a straight edge at right angles to the edge of N, and draw the point of a sharp penknife with its back towards him along the edge of the straight edge, a small square would be most handy for this purpose. Now, he may easily divide his plate J with a square and straight edge, or rule with 100th in. divisions thus: Place the back of the square against the edge of the straight edge with its blade over the divisions, fix the piece of zinc on the other side of the straight-edge, and with its surface to be divided on a level with the top of the straight-edge; he must firmly fix both the zinc and straight-edge together on a piece of board; first draw his long lines to bound his divisions as to length, as shown above J; there will be three of these long lines; he ought to polish the face of the zinc, or make it smooth before he begins. Now let him put the point of his sharp penknife with its back towards him into one of the divisions of his straight-edge, opposite to where he wishes to begin, on the left hand end of the lines he has to divide between, keeping the penknife about like he would hold a pen; now gently move the back of his square along the straight-edge till the blade just touches the penknife. Now draw a line on the zinc along the edge of the blade of his square; make this a long division—i.e., from the one long outside line to the other long outside line, and right across the middle long line. Now put the point of the penknife into the next 100th division on the straight-edge, and gently push the square up to it. Now draw another line on the zinc between two of the long lines only; this will be the first 100th division, and so on, at the 5 line, draw it so as to be a little longer than the 100ths, but not so long as the 10ths. Doubtless, his straight-edge will be divided in somewhat similar way. Let the amateur be careful to keep his penknife always exactly in the same position from the beginning to the end of his dividing operations, and let him not be discouraged if he fails with his first attempt by making mistakes in the length of his divisions, or in not getting them all the same width. Let him get another piece of zinc, and try again; he will be amply repaid for the loss of several pieces of zinc by the experience he will gain, and the pleasure of having divided his own plate. I thus divide mine with ease, and have no difficulty. To finish the description of this part, I may observe that the height from the table or bench to the middle of the shutter or hole in the chimney, or the divided plate J, all of which are on a level, is, in my case, 14in. This I find a convenient height.

I see I must leave the description of the lamp, and how to use the whole together, for my next letter; but this is no more than I expected. I would only most cordially invite any amateur to communicate direct with me as to any point I have not made plain. Thus I hope we shall clear up some of the old mysteries hanging about specula, and figuring, and Foucault's testings, &c., which were like so many bugbears frightening the amateur from so pleasing and instructive a pursuit; only let me remind him of what, perhaps, he learned as a boy: "If at first you don't succeed, try, try again"—i.e., if the object be worthy of the pursuit. **H. A. Wassell.**

Addenbrook Villa, Love-lane, Stourbridge.

THEORY OF THE ACHROMATIC OBJECT-GLASS.

[19923.]—I am endeavouring, in my humble way, to prepare an essay on the above subject. Our generous and accomplished master in practical matters, "Prismatique," has already promised assistance in the practical part; but he is at present, I know, very busy; and Mr. Wassell will, I have no doubt, go into the matter when he has finished with the mirror. Meanwhile, I think it will serve some useful purpose if I embody what relates to the theory in the form of an essay. Through the kindness of one correspondent, I have some particulars of the proportion of curves, and method of computing them, used by Tulley. If any other reader has similar particulars respecting the practice of other famous names, such as Fraunhofer, A. Ross, P. Dollond, and others, and would send some account of them, either to this paper, or through you, Sir, to me, it would furnish a history of the progress of the theory of the o.g., such as could be found in no other journal. I confine my request to particulars of the work of *deceased* artists, as the object of such an essay would be merely to show the development of the theory, not to give a particular account of the practice of any one artist. **Orderic Vital.**

AUTOMATIC AIR v. AUTOMATIC VACUUM BRAKES.

[19924.]—It has already been mentioned that the battle of the brakes is now being fought upon the question of which automatic brake shall be adopted, air or vacuum.

Before proceeding to express an opinion upon either of these systems, it will be of advantage to correct an idea somewhat generally held, that an automatic brake cannot be made to work without valves; it should be clearly understood that it is perfectly easy to construct such brakes to work with air-pressure or vacuum, without any taps, valves, or other so-called complicated parts; but all such brakes have and must have the fatal defect of being slow in action. After any brake trials or experiments have been conducted, the question is frequently asked, "Why is it that the Westinghouse Automatic brake always proves itself to be the best?" The reason is that its action is as nearly as possible instantaneous, the retarding power therefore is brought into effect with the least loss of time and distance; and this very great advantage is due to the use of the triple valve and high pressure. Mr. J. E. Harrison, the Engineer-in-Chief of the North-Eastern Railway, in his Report to the directors of that company, mentioned that the triple-valve had been made a regular bugbear by the opponents of the system, but he considered it a model of ingenuity and simplicity. The triple-valve is nothing more than a piston and slide-valve moving together as one piece. It is fixed between the auxiliary reservoir, which is charged with compressed air, and the brake cylinder; when the piston is pushed *up* the communication between the reservoir and cylinder is closed and the brake is "*off*," when, in consequence of the pressure in the main brake-pipe being reduced, the piston moves *down*, a direct passage is instantly opened, through which the air rushes from the reservoir to the cylinder, and applies the brake in a moment. This useful triple-valve has been called "complicated," but it will be seen that its action and construction are most simple. The next question which must naturally arise is, "If an automatic vacuum brake were constructed with a triple-valve, would the results obtained be equal to those of the Westinghouse Automatic Air brake?"

Most certainly they would not. A triple-valve would very greatly improve the action of a vacuum brake, but it is perfectly well understood that any amount of improvements in details can never make a bad system into a good one, nor overcome difficulties caused by the principle being wrong from the commencement.

In a letter which appeared in the English Mechanic, June, 1878, and in my pamphlet on "Railway Accidents," February 1881, I dealt fully with this question, and pointed out that the vacuum principle had the inherent defect of having only the pressure of the atmosphere to work with, whereas the compressed air system could be applied with any desired power.

The Westinghouse Automatic brake is generally worked with a pressure of 70 or 80lb. per square inch; this permits the pipes, cylinders, and other parts to be of small dimensions. On the other hand, a perfect vacuum gives a pressure of about 15lb. per square inch, but practically, a partial vacuum of 12lb. is all that can be obtained to work the brakes.

To make the low pressure of 12lb. exert the necessary power, the areas of the cylinders must be made fully six times as large to perform the same work as the high pressure of 70 or 80lb. There is no difficulty in *constructing* vacuum cylinders or sacks of the required size; but the very important point is, that every increase of size of course increases the cubical contents of the apparatus, and consequently a greater quantity of air has to be moved to apply and release the brakes; hence slow action *must* follow.

An automatic vacuum brake (as used on the Midland Railway for instance) is of such a large size to obtain the required power, that no less than 2,600 cubic inches of air must enter the pipes and cylinders upon *each carriage* in order to apply the brake with full power; therefore, in a train of 16 carriages, 41,600 cubic inches of air must pass into the apparatus, at the low atmospheric pressure, and it is stated that in practice this will occupy nearly *ten* seconds.

In the Westinghouse Automatic brake it is not necessary that the pressure in the brake pipe should be destroyed, but only that it should be reduced 20 per cent. Here, again, we see the great advantage of the triple valve: instead of having to discharge *all* the air from the brake-pipe, it is only necessary that the pressure should be reduced enough to cause the pistons in the triple valves to move down, and thus open direct communication between the auxiliary reservoirs and the brake cylinders, which instantly applies the brake with full force. In the Westinghouse system the space in the pipe and lower part of triple valve upon each carriage is about 330 cubic inches (and as only 20 per cent. reduction is required to put the brake *full on*), it follows that only 66 cubic inches of air per carriage have to be discharged, or upon a train of 16 vehicles, 1,056 cubic inches.

Having before us these details, it is easy to draw up the following summary.

Upon a train of 16 carriages, an automatic vacuum brake (having no triple valves) requires 41,600 cubic inches of air to be moved at a low pressure, which takes about ten seconds, whereas the Westinghouse Automatic brake only requires 1,056 inches of air to be discharged at high pressure, which practically takes about 1¼ second.

In this short summary we have, in a few words, the principle of the two systems clearly illustrated, and we can now give an answer to the question "why the Westinghouse brake has always proved itself to be the best." Instantaneous action, produced by the use of high pressure, controlled by that most ingenious piece of mechanism the triple valve. **Clement E. Stretton.**

Saxe-Coburg-street, Leicester.

RAILWAY BRAKES.

[19925.]—My attention having just been called to letter 19911, of Mr. C. E. Stretton's, on p. 109, I wish to correct an error or two into which he has fallen. It may be that he has been misled by the last Brakes Return; but not having seen this, I cannot say.

The system we have adopted is W. Parker Smith's Automatic Mechanical Brake. It is *not* a vacuum. It can be applied by driver or guard, and from any part of the train; it can also be applied at full power on three revolutions of the carriage or engine's wheels, or with any less power that may be desired; it can also at any moment be taken off or reduced, and reapplied. The connection between coaches is accomplished for attachment or detachment in a second or two. I myself believe it will be *the* brake of the future, satisfying, as I believe it does, *all* the requirements of the Board of Trade, who will shortly have a report thereon. It has run now with us about 5,000 miles without a failure. **J.**

Liskeard and Caradon Railway Company,
Liskeard, 8th April.

SCREWDRIVERS.

[19926.]—Seeing Sir Edmund Beckett's letter (19857, p. 63) describing his improvement in screwdrivers has induced me to send the method I use to prevent the ordinary screwdriver having such "persistence in slipping out of the nick."

When a screwdriver has a tendency to slip sideways, it is because it is ground too thin, and the point rests upon the bottom of the screw-nick. But if the point is ground very slightly taper, and to such a thickness that it will not quite reach the bottom, it will then jam tightly in, and have no tendency to slip. Of course, one driver cannot be made to do for very many different sizes of screws, but it can be made to do for several, and it is not well to use the same driver for many sizes on account of the width.

Journeyman Organ Builder.

L. AND N.W.R. "PRECEDENT" ENGINES.

[19927.]—As numerous correspondents have at different times asked for the dimensions of these engines, the following details may be acceptable:—

Cylinders .... 17in. by 24in.

	ft.	in.
Wheels, leading	3	6
,, driving	6	6
,, trailing	6	6
Wheel base..................	15	8
Distance between leading and driving-wheels	7	5

	ft.	in.		ft.	in.	
Firebox, length inside ..	4	9¼	top,	4	10⅝	bottom
,, breadth ,, ..	3	5¼	,,	3	6	,,
,, height from top of firebars ..	5	9¼				
Tubes, length	10	2¾				
,, diameter		1⅞				
,, distance between centres		2½				
,, number	198					

	ft.	in.
Boiler, diameter outside..........	4	1¼
Blast-pipe, diameter inside		4⅞

Working pressure ...... 120lb. sq. in.
Heating-surface, tubes .. 980 sq ft.
,, ,, firebox 103·5 sq. ft.

Total .... 1083·5
Grate area .... 17·1 sq. ft.
Area of tubes ...... 2·96 sq. ft.

	Tons.	cwt.
Weight, empty	30	10
,, working order	32	19
,, ,, driving-wheels	11	10

Tender—Wheels, 6; diameter, 3ft. 6in. Water, 1,800 gallons.

	Tons.	cwt.
Weight, empty	12	1
,, full	24	5
Total weight of engine and tender in working order..............	57	4

The driving and trailing-wheels are fitted with steam-brake, and tender with hand-brake, also Ramsbottom's apparatus for filling the tender while in motion.

Perhaps some correspondent can tell me why a "Precedent" engine is working the 4.0 p.m. fast express from Euston, as a "Lady of the Lake" used always to be used; also whether the "Charles Dickens" is a new engine?

E. W. J.

MEDICAL REPLIES.

[19928.]—Turkish Bath for Home Use (46295).—A sort of steam closet into which steam—suitably guarded and under control of patient—could be let while the patient sat with his head out, is probably the cheapest and most useful approximation to a Turkish bath. I have seen an admirable home-bath constructed by Dr. Edward Haughton, of Upper Norwood, and I have no doubt that any reader of the English Mechanic who called upon or wrote to Dr. Haughton, would get just the help now asked for. Dr. Haughton has paid great attention to such domestic baths, and to therapeutic bathing of all sorts.

Skin Disease. (46556).—"Sufferer" is probably the subject of a rare disease named "sycosis," and one which, when allowed to become inveterate, is very difficult to cure. Sycosis is a disease of the hair-follicles of the beard allied to true ringworm of the hairy scalp, and it consists of a cryptogamic growth, which infests the bulbs and follicles of the hairs, causing eruptions of which each hair is the focus. Blood medicines are quite useless, as the disease is as purely local as is the itch itself. Plucking out the hairs generally and continuously, and poulticing the skin every night with a linseed poultice, smeared slightly with softsoap, and then washing skin carefully clean, and applying some agent which will soak into the hair-follicles, and kill the vegetable parasites which now infest the texture of the skin, is the line on which cure will be arrived at. But this treatment wants delicate handling, and I can only indicate the guiding principle here. Just as a gardener will kill weeds on a gravel-walk by sprinkling the surface with salt, so these parasites must be killed in the texture of the skin. But it is of no use to smear applications on the outside of masses of scab; all such matters must be cleared away by epilation and preliminary poulticing.

Deafness (46566).—Read last week's reply.

Stoppage of the Eustachian tube means obstruction of the passage which leads from the drum of the ear into the throat on a level with the floor of the nostril. 2. Probably needs constitutional treatment for the purpose of producing a healthier condition of the lining membrane of the tube. Consult the best doctor in your neighbourhood, and do not attempt to deal with the matter yourself.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

DYNAMO-MACHINE.

[19929.]—Further particulars from "Conrad" would be very acceptable. 1st. Size of field-magnets, quantity and size of wire on them, purpose for which dynamo is used—plating or lighting? Are the field-magnets connected or independent of each other, and does the armature-spindle work through holes in the poles S. and N.? From the sketch, I should take it the field-magnets were wound from end to end, passing at the back of the circular pole, and connected only at one end; and it appears to be a very simple affair to construct. But full particulars would greatly assist amateurs in making one. A sketch, more in detail, showing commutators and connections of wires from bobbins, and the manner the current is taken from armature through field-magnet wires, and thence to the work, would be a great assistance. Also, the amount of power required to work it, and amount of current produced under favourable circumstances. Any information as to dynamos is now very welcome to the readers of the "E. M."

H.

ORNAMENTAL SLIDE-REST.

[19230.]—In the ornamental slide-rest of "F. W. G." (19872), the principal advantage over Holtzapffel's pattern seems to be in the tool-box, which is better adapted for ordinary cutters, though it may be a question whether it is as well fitted for the reception of drills and eccentric cutters. There are two or three points, however, in this slide-rest, which I should like to bring under "F. W. G.'s" notice.

1. As to the V-shaped thread of the leading-screw.

A square thread works to better advantage in producing motion in a slide-rest; and in the case of backlash, caused by wear, I fail to see how the arrangement proposed (H) will remedy it. The form of the space between the threads of a V-screw is a V when new, and a wider V with the point cut off when it is worn, approaching, in fact, the form in a square-threaded screw, and as clamping will not remedy backlash in a square screw, it will fail to do so in the V-screw, for the same reason. There would seem, therefore, to be no advantage in favour of the V-screw.

The best way to prevent backlash is to cut the nut in two, transversely, and join it again by four screws in the corners (the nut should be drilled and tapped for the four screws before sawing it in two), by means of which it can be clamped to the threads of the leading-screw; but in a direction perpendicular to that proposed by "F. W. G."

2. Would not the lever M work much better if the pillar O were fixed in the hole P, instead of in the lever?

3. It is proposed to raise the level of the slide-rest, where required, by washers, instead of a "screw ferrule."

I think, if "F. W. G." examines one of Holtzapffel's ornamental slide-rests, he would allow that the beautiful working of the "screw ferrule" is a welcome substitute for the innumerable washers that would be required to produce a like result in raising the level of the rest.

Another of your correspondents brought under our notice, a few weeks ago, a compound oval and eccentric chuck, the oval chuck being made eccentric by clamping the sliding portion at the proposed eccentricity with screws. As there is always a small space between the two surfaces, it occurs to me that there is great danger of bending one, or both, by the process, and so completely spoiling the oval chuck. The danger would be diminished by inserting a thin piece of brass between the surfaces; but there would still be risk of damage.

M. A.

"JUMPING" OF ETHER STOPPERS.

[19931.]—Mr. W. Broughton, referring (letter 19900, page 107) to the jumping out of the stoppers of bottles containing ether and other volatile liquids, recommends the use of an india-rubber finger-stall drawn like a cap over the stopper and neck of the bottle. A cheaper and equally effective remedy is to loosely wire the stopper down, so that it may have about a quarter of an inch of play. This method has an advantage over the former, in that it allows vapor to escape when the pressure within the bottle becomes excessive. When any of the contained liquid is required for use, the wire can easily be pushed to one side, and as easily replaced.

Alfred W. Soward.

RAMSDEN'S DIVIDING-MACHINES.—
Part II.

[19932.]—"The wheel was now taken off the lathe, and the bell-metal piece D was screwed on as before directed, which, after this, ought not to be removed.

"From a very exact centre a circle was described on the ring C, about 4-10th of an inch within where the bottom of the teeth would come. This circle was divided with the greatest exactness I was capable of, first into five parts, and each of these into three. These parts were then bisected four times; that is to say, supposing the whole circumference of the wheel to contain 2,160 teeth, this being divided into five parts, each would contain 432, which, being divided by three, each would contain 144, and this space bisected four times would give 72 – 36 – 18 – 9; therefore, each of the last divisions would contain 9 teeth. But, as I was apprehensive some error might arise from quinquesection and trisection, in order to examine the accuracy of the divisions, I described another circle on the ring C (Fig. 7) 1-10in. within the first, and divided it by continual bisection, as 2,160, 1,080, 540, 270, 135, $67\frac{1}{2}$, $33\frac{3}{4}$, and as the fixed wire (to be described presently) crossed both the circles, I could examine their agreement at every 135 revolutions (after ratching could examine it at every $33\frac{3}{4}$); but not finding any sensible difference between the two sets of divisions, I for ratching made choice of the former, and as the coincidence of the fixed wire with an intersection could be more exactly determined with a dot or division, I, therefore, made use of intersections on both sides before described.

"The arms of the frame L (Fig. 7) were connected by a thin piece of brass, of $\frac{3}{4}$in. broad, having a hole in the middle 4-10in. diameter; across this hole a silver wire was fixed, exactly in a line to the centre of the wheel; the coincidence of this wire with the intersections was examined by a lens of 7-10in. focus, fixed in a tube which was attached to one of the arms of L. Now, a handle or winch being fixed on the end of the screw, the division marked 10 on the circle K was set to its index, and by means of a clamp and adjusting-screw for that purpose, the intersection marked 1 on the circle C was set exactly to coincide with the fixed wire. The screw was then carfully pressed against the circumference of the wheel by turning the finger-screws *s*; then, removing the clamp, I turned the screw by its handle 9 revolutions till the intersection marked 240 came nearly to the wire. Then, turning the finger-screw *s*, I released the screw from the wheel, and turned the wheel back till the intersection marked 2 exactly coincided with the wire, and, by means of the clamp before mentioned, the division 10 on the circle being set to it index, the screw was pressed against the edges of the wheel by the finger-screw *s*, the clamps were removed, and the screw turned 9 revolutions till the intersection marked 1 nearly coincided with the fixed wire; the screw was released from the wheel by turning finger-screws *s* as before, the wheel was turned back till intersection marked 3 coincided with the fixed wire; the division 10 in the circle being set to its index, the screw was pressed against the wheel as before, and the screw turned nine revolutions, till intersection 2 was nearly coincident with the fixed wire, and the screw released, and I proceeded in this manner till the teeth were marked round the whole circumference of the wheel. This was repeated three times round, to make the impressions deeper. I then ratched the wheel round continuously in the same direction, without ever disengaging the screw, and in ratching the wheel about 300 times round, the teeth were finished.

"Now it is evident that if the circumference of the wheel was even one tooth, or ten minutes, greater than the screw would require, this error would, in the first instance, be reduced by 1-240th part of a revolution, or two seconds and a half, and these errors, or inequalities of the teeth, were equally distributed round the wheel at the distance of nine teeth from each other. Now, as the screw in ratching had continually hold of several teeth at the same time, and thus constantly changing, the above-mentioned irregularities soon corrected themselves, and the teeth were reduced to a perfect equality. The piece of brass which carries the wire, was now taken away, and the cutting-screw was also removed, and a plain one (hereafter described) put in its place. At one end of the screw was a small brass circle, having its edge divided into 60 parts, numbered at every sixth division, as before mentioned. On the other end of the screw is a ratchet-wheel C, having 60 teeth, covered by the hollow circle *d* (Figs. 4 and 5), which carries two clicks, that catch upon opposite sides of the ratchet-wheel. When the screw is to be moved forwards, the cylinder *s* turns on a strong steel arbor, F, which passes through, and is firmly secured to, the piece *y*; this piece, for greater firmness, is attached to the screw-frame G, by the braces *v*. A spiral groove, or thread, is cut upon the outside of the cylinder *s*, which serves both for holding the string and also giving motion to the lever I, on its centre, by means of a steel tooth *n*, that works between the threads of the spiral. To the lever is attached a strong steel pin *m*, on which a brass socket *r* turns; this socket passes through a slit in the piece *p*, and may be tightened in any part of the slit by the finger-nut *f*. This piece serves to regulate the number of revolutions of the screw for each tread of the treadle R.

"T (Fig. 1) is a brass box, containing a spiral spring; a strong gut is fastened and turned three or four times round the circumference of this box; the gut then passes several times round the cylinder *s*, and from thence down to the treadle R. Now, when the treadle is pressed down, the string pulls the cylinder *s* on its axis, and the clicks, catching hold of the teeth of the ratchet, carry the screw round with it, till by the tooth *n* working in the spiral groove, the lever I is brought near the wheel *d*, and the cylinder stopped by the screw-head *x* striking on the top of the lever I; at the same time, the spring is wound up by the other end of the gut passing round the box T (Fig. 1).

"Now, when the foot is taken off the treadle, the spring unbending itself pulls back the cylinder, the clicks leave the ratchet and screw at rest, until the piece *t* strikes on the end of the piece *p*; the number of revolutions of the screw at each tread, is limited by the number of revolutions the cylinder is allowed to turn back before the stop strikes on the piece *p*.

"When the endless screw was moved round its axis with a considerable velocity, it would continue this motion a little after the cylinder *s* was stopped. To prevent this, the angular lever *η* was made, that when the lever I comes near to stop the screw *x*, it, by a small chamfer, presses down the piece *x* of the angular lever. This brings the other end *y* of the same lever forwards, and stops the endless screw, by the steel pin *u* striking upon the top of it. The foot of the lever is raised again by a small spring pressing on the piece V.

"D, two clumps connected by the pin *a*, slide one on each arm of the piece L, and may be fastened at pleasure by the four finger-screws *e*, which press against steel springs, to avoid spoiling the arms. The piece *q* is made to turn without shake between two conical-pointed screws *f*, which are prevented from unturning by tightening the finger-nuts *n*.

"The piece *m* is made to turn on the piece *q* by the conical-pointed screws *s*, resting in the hollow centres *c*.

"As there is frequent necessity to cut divisions on inclined planes, for that purpose the piece *γ*, in which the tracer is fixed, has a conical axis at each end, which turns in half-holes. When the tracer is set to any inclination, it may be fixed there, by tightening the steel screws *β*."

Description of the Engine by which the Endless Screw of the Dividing-Engine was Cut.

Fig. 9 represents the engine of its full dimensions, seen from one side.

Fig. 8 shows the upper side of the same, as seen from above.

"A represents a triangular bar of steel, on which the triangular holes in the pieces B and C are accurately fitted, and may be fixed at any part of the bar by means of the screws D.

"E is a piece of steel, whereon the screw is intended to be cut, which, after being hardened and tempered, has its pivots turned into the form of two frustums of cones, as represented in the drawing of the dividing engine, Fig. 5. These pivots are exactly fitted to the half-holes F, T, which are kept together by the screws *z*.

"H represents a screw of untempered steel, having a pivot I, which turns in the hole K. At the other end of the screw is a hollow centre, which receives the hard conical point of the steel pin *m*. When this point is sufficiently pressed against the screw, to prevent its shaking the steel pin *m* is fastened by tightening the screws Y.

"N is a cylindrical nut, movable on the screw H, which to prevent shake may be tightened by the screw O. This nut is connected with the saddle piece P by means of the intermediate universal joint W, through which the arbor of the screw H passes. A front view of this piece, with a section across the screw arbor, is represented at X. This joint is connected with the nut by means of two steel slips *s*, which turn on pins between the cheeks T on the nut N. The other ends of these slips *s* turn in like manner on pins (*a*). One axis of this joint turns in a hole in the cock (*b*), which is fixed to the saddle piece, and the other turns in a hole *d*, made for that purpose in the same piece in which the cock *b* is fixed. By this means, when the screw is turned round, the saddle piece will slide uniformly along the triangular bar A.

"K is a small triangular bar of well-tempered steel, which slides in a groove of the same form, on the saddle-piece P. The point of this bar or cutter is formed to the shape of the teeth intended to be cut on the endless screw. When the cutter is set to take proper hold of the intended screw, it may be fixed by tightening the screw *e*, which clamps the two pieces of brass, G, upon it.

FIG. 8.

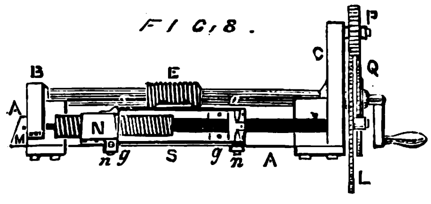

FIG. 9.

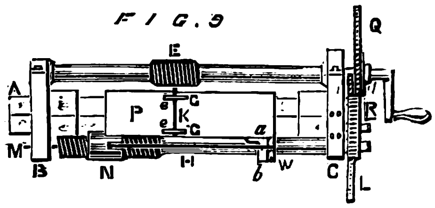


"Having measured the circumference of the dividing-wheel, I found it would require a screw about one thread in a hundred coarser than the guide-screw H. The wheel on the guide-screw arbor H, and that on the stud E, on which is the screw to be cut, are proportioned to each other to produce this effect, by giving that on the arbor I, 198, and that on the arbor Q, 200. These wheels gear with each other by means of an interior-wheel R, which serves also to give the threads on the two screws the same direction.

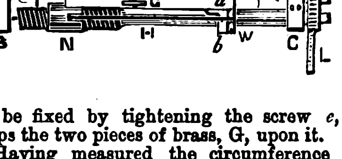
"The saddle-piece P, is confined on the bar A, by means of the piece *q*, and may be made to slide with a proper degree of tightness by means of the screw *n*." **Orderic Vital.**

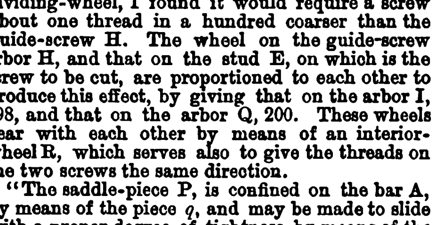
(*To be continued.*)

ATTACHMENT TO ELECTRIC-BELL FOR CONTINUOUS RINGING.

[19933.]—In the hope of benefiting some of the readers of the "E.M." I beg to send the following method of producing continuous ringing from an ordinary electric-bell. The method works well; is inexpensive; and anyone with very ordinary intelligence, could make and fix one for himself. Of course the bell must have a contact breaker; A, bell; B, hammer, in the centre of which is screwed or soldered a piece of metal projecting outwards half an inch. The head of my hammer is a flat, circular one, with a hole in centre; *c*, piece of brass hung loosely on the screw, to which wire is attached, leading to bell as shown; D, screw and wire attached leading to battery. On the bell being rung, the oblong piece of brass, *c*, is liberated, falling on to D, making a new circuit producing continuous ringing until *c* is lifted up.

J. W. Fisher.





OVENS HEATED BY GAS COKE.

[19934.]—The systems are various for raising heat in more or less confined spaces to the baking points of breads. We find them ranging from the expiring wood ash heap of the Australasian bushman, the camp oven suspended over, or immersed in, more lively embers, the many shapes of ship ovens, mostly iron, heated by hot air from the cooking fires, the movable firegrate burning coal in country places, and still largely used, and the common furnace fixed in one corner of the oven. Over these, and claiming to rank as scientific, we have the complicated hot-air ovens of Paris, the complex system of iron pipes containing water, radiating heat after being heated to a high temperature by placing one end of the pipes, spiral shaped, in a burning furnace, and lastly, though not including all, the almost automatic "travelling" or biscuit oven.

Something more cleanly than the first, and more simple and inexpensive than the last three is required by bakers, who, as a rule, are not what could be called rich, are generally tenants, and are excusably reluctant to spend in experiments on their landlords' property. Yet it is a mystery to some minds why bakers in the south, and particularly in London, cling to the use of smoky coal, and frequently waste money in altering the furnace and fittings to consume smoke before it passes from the oven. While there is, and rightly too, a statute to prohibit the excessive emitting of smoke in towns, there is no law to compel the use of smoke-producing fuel. How then, it may be asked, shall we heat our ovens? This problem, and others of more vital interest in the production of bread, the canny and matter-of-fact Scotch baker has solved years ago. And it is curious that the solution of "no smoke and yet plenty of heat" was discovered, not where fuel was dearest, but in Glasgow, I believe, in the heart of coal-fields. The bakers there and throughout Scotland find there is no difficulty, on the contrary, greater ease, cleanliness, and far less cost in heating ovens with smokeless fuel, and that fuel they find in perfection in gas-coke of fine quality. Whether the ovens of the future will be so heated, or by hot-air from a fire without the oven, or by air-gas burning outside or inside, remains to be seen. But before entering into details of these coke-heated ovens, I would like to make a few remarks on the experiments with a model gas-air oven at the Smoke Abatement Exhibition, South Kensington, before a deputation of master bakers. The substance of this letter has appeared in the *Miller*.

Practical bakers who have read the lucid report of Mr. Pringle will, I think, agree with me that these experiments are very inconclusive for or against the use of air-gas for oven-heating. My remarks, I may be permitted to observe, are founded on the report, and also an experience of seven years regulating oven heats with pyrometers, heating a number of ovens from a new and damp state, and the daily heating of a steam-press with air-gas three times the reported size of the model oven at South Kensington. Such experience being given for what it is worth, it seems to me, then, that the failure of the model oven to bake bread to the satisfaction of the deputation was mainly due to the want of several days' prolonged and thorough heating of the mass of lime and brick, and the low heat, on the day of the inspection, before the dough was put in. Those who have had experience of heating up new-built ovens know that three or four weeks pass of daily heating and working before the bottom crust is at all satisfactory. Even if the model oven had been heated daily for weeks before the 8th and 9th February, no other results, I venture to say, could have been obtained from the heats given in Mr. Thomson's memo. than those reported by Mr. Pringle. The model, it seems to me, has not got fair play. Lighting the gas supplying it on the 9th February, with 140 deg. left from the previous day, and putting in dough when the heat was 345 deg., was unskilful heating, and the heat too low. The oven should have been heated to 600 deg.—50 deg., allowed to cool to 350 deg., and the dough put in. When, for instance, our last batches of loaves are out on Saturday, the pyrometers show 340 deg. of heat left, and on the following Monday, before lighting, they have never been seen lower than 250 deg. An hour and a half after lighting they show 650 deg., when the batch is being put in 400 deg., while in 370 deg.—60 deg., and 350 deg. when withdrawn. These heats are for close-packed 4-lb. loaves, for open-placed crusty-baked loaves 50 deg. less would be.

Bakers, it will be observed from Mr. Pringle's report, are not the only men who work by rule-of-thumb. Knowing how reliable, cheap, and common Messrs. W. H. Bailey and Co.'s pyrometers are, it is surprising to read of scientific exhibitors using a mercurial thermometer to test the heat of an oven requiring to be heated over the boiling-point of mercury. And the effort to produce saleable or eatable pastry out of an oven at 320 deg., from which bread had just been withdrawn, deserved success but hardly comment. These are errors of manipulation, and might have been avoided by the employment of a practical baker skilled in oven pyrometer heats. But Mr. Pringle's report shows that the model has vital structural defects, in the admission of hot air by the roof only, and the want of indicated means of ventilation to carry off the waste poisonous products of combustion. This latter, in the underground, low-roofed, badly ventilated London bakehouses, would be a fatal objection. The experiments of numerous gas-air experts have long since shown that double the heat required by the baker can be got from non-illuminating gas. The difficulty, then, ventilation being provided for, lies in the distribution of the required heat. While the admission of hot air by the roof only to the small model might, by proper heating, be sufficient for it, it is difficult to see how a full-sized oven could be so heated to bake crumby bread. I am assuming that the sole of the oven rests on a solid bed. If the space beneath the sole is hollow, then the remedy will be found in a study of the structural details of the Paris hot-air ovens. These are more or less hollow, and the heat beneath the glazed tile sole, resting on a framework of iron, is kept up by hot air from chambers maintained continuously at a high temperature, and admitted by a damper or dampers into a network of hollow tubes. Several of these ovens will be found illustrated in "Cassell's Household Guide," Vol. III. Except in one instance, I am not aware that these hot-air hollow or cellular ovens have been used successfully for baking close-packed loaves. The instance I refer to, and I only write from report, is that of a bakery in Dunfermline, where one or more of these ovens, heated with hot air from the outside, are in use, and the sole is not stone, brick, or tile, but *iron*.

Meantime, and with an earnest wish for success to the inventors of the model oven to perfect the application of controlable heated air, and an apology should my foregoing remarks require it, I would beg the attention of my brother craftsmen to the accompanying working plan (Fig. 2) and section (Fig. 1) of a line of three gas coke-heated ovens. They are in operation in Dundee, where almost all the ovens are on the same plan and coke heated, as also in Edinburgh, Glasgow, and throughout Scotland.

FIG. 1. SECTION THRO A.B.

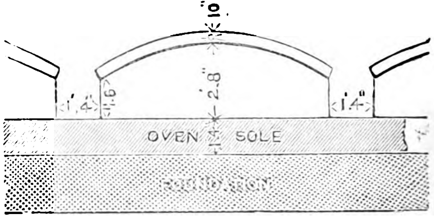


FIG. 2. PLAN.

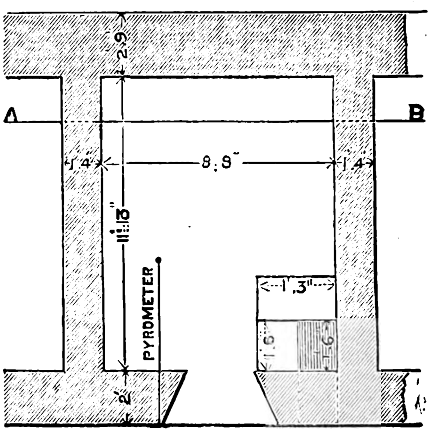


A glance at the lower right-hand corner of the plan will show that apart from breadth in proportion to length, which is a matter of convenience for working and not indispensable, the main difference between these ovens and the usual coal-heated London oven is seen in the position of the firebars. These bars are, as shown in plan (Fig. 2), within the oven. In the usual coal furnace they are within the front wall, and not inside the oven. In these coke ovens the space where the coal firebars would be is a hollow or "blind furnace," a foot square, lined top, sides, and bottom with firebrick, into which any burning coke may be drawn before the batch is put in. Also by this blind furnace which is fitted with a special iron frame and outside door, the firebars can be cleared of clinkers, and new bars replace old ones; but coke is usually fed to the fire by the oven mouth. A sheet-iron fender circling the fire prevents the coke and ash from spreading over the oven. The ashpit is beneath the firebars, and has an opening from the outside front. And the vents, not shown in plan, over the oven mouth, and the blowing vent, opening within the oven, fitted with the usual damper, are the same as in a coal furnace oven. When a pyrometer is fitted it should be placed on the side furthest from the fire, a little lower than the top of the oven mouth. But this will depend on the height of the roof. If the roof is, say, 30in. at the highest above the sole, the pyrometer should pierce the wall at 15in. or midway.

The heating of these ovens goes on all night, and gives no work or trouble to heat in the morning. This to men working in the stifling and sickening heat of summer in underground bakehouses, where one or many ovens are being heated so fiercely that the furnace doors outside are often of a red heat, would be no slight boon, to say nothing of the time saved, and the lighter work to those who have charge of the oven. Sufficient coke is put on in the afternoon before leaving off work, and the door left slightly open, or the door shut and the damper withdrawn a bit, and the coke burns slowly down to an impalpable dust, leaving the walls and roof as white as chalk. A clean out with damp scuffle (swab on end of long pole) is all that is required to prepare the oven to bake morning rolls, another clean out, and the batch may be put in when ready. The heat then should be between 350 and 400 degs., and as the firing or heating has been slow it is deep and lasting, baking the full of the oven of close-packed 2lb. loaves in one and a-half hour, or 4lb. loaves in two hours.

At a very slight expense for a new and special furnace casting, with door attached and firebars to match, the present coal furnace, with the bars within the wall, will heat the oven with gas-coke. My ovens are so heated, and have the firebars within the wall. They were unfortunately built before I saw this plan with bars within the oven. The front walls are 2ft. 6in. instead of 2ft., the furnace 15in. wide and flush at the top with the roof of the ovens. The furnace-door casting enters in 8in., the firebars 1ft. 10in., thus the door casting and bars together are exactly 2ft. 6in., the width of the front wall. My ovens being wider and shorter than that in the plan, it is easier to feed coke by the furnace door than by the oven-mouth; we can either use coke, coal, or wood, but with coke alone, after lighting up with wood, we find no difficulty in the morning in heating the ovens as thoroughly as with coal. This presupposes coke of fine quality and kept dry. As it gives out an intense heat and the fire is so near the outside, I do not think it advisable to put on coke in the afternoon to burn all night. But were I to build again, it would certainly be as this plan shows. Gas coke costs 3s. 6d. per ton at Glasgow. A ton will heat one oven in full work for near three weeks. **W. A. Thoms, F.R.M.S.**

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45809.]—**Lunar Craters.**—In reply to E. T. Scott, I would ask him to reperuse my letters 19086, p. 570, August 19, 1881, and 19463, p. 301, Dec. 2, 1881. We must accept the verdict of experts as to the almost total absence of air and water (as liquid), on the moon's surface. In cooling steadily she has shrunk and solidified (at the surface at least), and what I urge is this—as this cooling goes on, the later traces of moisture are gradually ejected from the somewhat warmer interior, causing the mist and haze seen by observers, and that after condensation it falls around the orifice in a circle to form a piled ring, and that as the moon cools more and more, the phenomena is less and less energetic in the main, and may end at last in simply causing mounds or lumps, while in former times, when the ejection was more copious and forcible, it formed vast walls or circles of mountains (condensed precipitate); solid matter, ejected at times in a rush, being piled close to the orifice, as in the central cones. The surface modelling of our earth is mainly due to sub-aërial and sub-aqueous erosion, and not due to precipitate piled up, except on our poles. The forms of our earth are easily understood, whereas the peculiar surfacing on the moon, at least as far as the craters and walled plains go, is unlike terrestrial forms, except volcanic. I take it that her peculiarity in this respect is due to an ejection (perhaps for ages) of the moisture from the interior, and its deposit on the exterior in the characteristic rings, and latterly lumps. Hence, also, the vapour and haze seen.—S. E. PEAL.

[45892.]—**Calorific Intensity (U.Q.)**—The problem is: Given a certain number of units of heat which would be given off from the combustion of 1lb. of fuel, say, olefiant gas, with the temperature of the gas before combustion, and the quantity of air necessary to consume the gas, to find the temperature of the products of combustion. Let us take as an example the fuel mentioned—namely, olefiant gas, and set out the facts which will form the basis of our calculation. The formula of the substance in question is C_2H_4, and it contains 24 parts by weight of carbon combined with 4 of hydrogen, or, expressed centesimally, 85·71 of the former to 14·29 of the latter. The units of heat evolved in the combustion of C_2H_4 are, in round figures, 12,000 (11,858, Favre and Silbermann; 12,030, Dulong); in other words, the heat evolved by the burning of 1lb. of olefiant gas would raise about 12,000lb. of water from 0° C. to 1° C., or (although in strictness it is not a fair deduction), 1lb. of water from 0° C. to 12,000° C. The products of the combustion are carbonic acid (CO_2), and water (H_2O). Carbonic acid is produced by the combination of 12 parts by weight of carbon and 32 of oxygen, water by that of 2 of hydrogen and 16 of oxygen. Therefore, 1lb. of olefiant gas produces by its combustion 3·14lb. of CO_2 and 1·29lb. of H_2O, thus:—

12 parts of C oxidise to 44 of CO_2
1 ,, ,, ,, $\frac{44}{12}$,,
·86lb. ,, ,, $\frac{\cdot 86 \times 44}{12} = 3{\cdot}14$lb. of CO_2

And—
2 parts of H oxidise to 18 of H_2O
1 ,, ,, $\frac{18}{2}$,,
·14lb. ,, ,, $\frac{\cdot 14 \times 18}{2} = 1{\cdot}29$lb. of H_2O.

It requires (3·14 × 1·29) − 1 = 3·43lb. of oxygen for its complete combustion, which quantity is contained in 14·96lb. of air thus:—

22·92 parts of O are contained in 100·00 of air
1 ,, ,, ,, $\frac{100}{22{\cdot}92}$,,
3·43lb. ,, ,, ,, $\frac{3{\cdot}43 \times 100}{22{\cdot}92} =$
14·96lb. of air.

This air contains 14·96 − 3·43 = 11·53lb. of nitrogen. The specific heat of carbonic acid is 0·2164, of steam 0·477, and of nitrogen 0·244. That is if a certain amount of heat is necessary to raise a given weight of water through one degree C, only ·2164 of that heat is required to raise the same weight of carbonic acid, only 0·477 of it to raise the same weight of steam, and only 0·244 of it to raise the same weight of nitrogen through the one degree. Now to our calculation. We start with a heat-proof vessel containing 1lb. of C_2H_4, together with 14·96lb. of air, all at (say) 0° C. After the combustion we have 3·14lb. of CO_2, 1·29lb. of H_2O, 11·53lb. of N. Required the temperature. If CO_2, H_2O (steam), and N had each the specific heat of water, the answer would be (subject to a correction referred to later on) 1,000 / 15·96 = 752° C; but, unfortunately for the simplicity of our calculation, they have not. Remembering the meaning of the term "specific heat," it will be evident that if we multiply the weights of the products of combustion by the respective specific heats of those products, we shall obtain figures which represent, so far as specific heat is concerned, equivalent amounts of water. Our 3·14lb. of CO_2 are equivalent, then, to 3·14 × 0·2164 = ·68lb. of water, our 1·29lb. of steam to 1·29 × 0·477 = ·61 of water, and our 11·53lb. of nitrogen to 11·53 × 0·244 = 2·81lb. of water; or our 15·96lb. of mixed gas are equal in specific heat to 4·11lb. of water. We must, therefore, divide our 12,000 heat units (which, we remember, would raise 1lb. of water through 12,000° C.), not by 15·96, but by 4·11. On doing so, we get as answer, 2922, which would seem to be the temperature in degrees centigrade of the mixed gases in our vessel. But it is not, because at this high temperature the steam produced in the experiment remains as such. The 12,000 units of heat are only evolved where the steam is permitted to condense; where it is not so permitted, as in the present instance, this figure must be reduced by the value of what is usually called "the latent heat of steam," or, in other words, the heat absorbed in the mechanical work of transforming water at 100° C. into steam at the same temperature. The "latent heat" of a pound of steam is equivalent to the heat required to raise a pound of water through 537° C. As in our experiment we have 1·29lb. of steam, the heat latent in it would, if used in raising the temperature of a pound of water, do so to the extent of 1·29 × 537 = 692·73° C. Deducting this figure from our 12000, we get 11307·27; dividing this, as before, by 4·11, we obtain 2751, which is the temperature required. If we had started with any temperature other than zero, our final temperature would have required correction by that amount. I have given the steps of the calculation in detail; but, in actual practice, such questions are worked by formulæ. For the case of a compound of carbon and hydrogen burned in atmospheric air the formula is:—

$$I = \frac{kc + h\,(k' - 4833)}{c\left(\frac{11}{3}s + 9\,s'\right) + h\,(26{\cdot}63\,s' + 9\,s'')}$$

where I = calorific intensity of products of combustion expressed in degrees centigrade, k = calorific power of carbon expressed in units of heat evolved, c = weight of carbon in reference to any unit, h = weight of hydrogen in reference to the same unit, k' = calorific power of hydrogen also in units of heat evolved, s = specific heat of carbonic acid, s' = specific heat of nitrogen, s'' = specific heat of steam. It will be seen that it is unnecessary to determine experimentally the calorific power of the particular compound under investigation; it is the sum of the calorific powers of the constituents of that compound, and these latter are, therefore, used in the formula.—ALFRED W. SOWARD.

[45907.]—**Automatic Musical Instruments.** Since my reply on p. 12, I have discovered that the publication of Needham's design, on p. 514 of this paper for Aug. 2, 1878, was preceded by a picture of the McTammany organette in Frank Leslie's paper for July 13, 1878. The organette is there represented as being worked by the feet of the inventor, who is also playing the violin. The instrument is one of the large size, blown by ordinary pedals, and a party of ladies and gentlemen are present. The patent, I believe, dates from the caveat, which was filed some time in 1876, whereas Needham's was not filed until 1877. I hope that information may be of use to "Nun. Dor." I see that "A. S. L." claims to be the first to combine reeds and perforated paper, which may probably be the fact, but I gather that he used *pressure* bellows, which sufficiently accounts for his indifferent success. Had he tried the suction principle, he would have succeeded. McTammany's instrument uses springs and levers with pins to enter the perforations, and is made with reeds or pipes (the latter being called melopeans). The orguinette illustrated on p. 105, No. 733, shows only one of the forms patented, and its name indicates that it is not altogether an original production—org*u*inette would not have been used had "organette" been available.—GRAY'S INN.

[46127.]—**Snails.**—There is a kind of slug or shelless snail which used to be considered good for lung-diseases. It is a sort of silver-grey colour, very smooth and tender, and seldom more than about an inch long, and is called in Ireland, "Drouktheen." I have known people who would swallow them like oysters as fast as they could catch them, and considered them very beneficial to weak lungs. Another way of using them was to put a lot in a cup, and put powdered loaf-sugar on them, when (if the right sort) they will melt entirely away, turning into a syrup, which is then taken, and to which used to be attributed all the virtues, and more, which are now claimed for cod-liver oil, which seems to have superseded it. I have not heard of it for a long time, but forty years ago or so many believed in it and used it.—G. J. H.

[46161.]—**Pumping to Pressure.**—I cannot, unfortunately, refer to the number containing the particulars you gave of your case; but, if you will advertise your address, I will do my best to help you all I can.—LABOR OMNIA VINCIT.

[46210.]—**Wheatstone Bridge.**—"R. P." says "lead wire from between the two 10-ohm coils to E." Surely this is wrong. Should it not be led to battery contact C? Will "R. P." give dimensions of his astatic galvanometer.—A. A. W.

[46218.]—**Solder.**—An easy-running silver solder is made of fine silver 1oz., shot copper 6dwt. 12gr., and spelter 2dwt. 4gr.; a common solder is made of silver 20, shot copper 12, and spelter 3 parts. The spelter should be as pure as possible.—G. S. H.

[46241.]—**Slate Roof.**—The answer to this question would appear to be because the rule has been found to give an accurate result. Where is the rule given? There should be an explanation, which is probably that part of the weight is taken up as thrust.—B. F.

[46260.]—**Railway-Brake Formula.**—How can such formula be devised? The distance run in feet in a given time must vary to a certain extent with the speed, and also with the condition of the rails; similarly if distance is known, you must have the speed before you can find the time, and then only approximately.—NOT A DRIVER.

[46273.]—**Making Small Tin Goods.**—The goods referred to by "C. R. K." are stamped up, and cannot be done with simple tools: machines and power are required.—NUN. DOR.

[46283.]—**Timber.**—Laslett's "Timber and Timber Trees, Native and Foreign," Macmillan and Co., would suit, I think, though if I recollect, it does not give prices. Mr. Laslett was Inspector of Timber to the Admiralty for many years.—NUN. DOR.

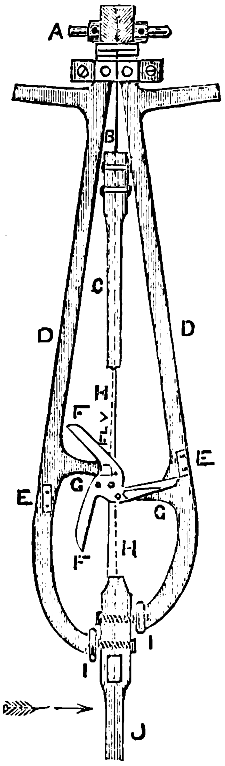
[46296.]—**Harmonium or Organ.**—I noted the query of "Beta," and his appeal to myself, amongst others, but have been unable to reply before. I am glad to see, however, that he has received some excellent replies. I suppose his instrument has the ordinary 10in. keys, and the question is, How to add two rows of reeds—a question which is complicated by the fact that the instrument has a sub-bass. The best plan would, I think, be to sell and begin again; but as that is not the question, we will see what can be done. I should not think of reversing the A. O. reeds and putting them under pressure of wind; but I see no reason why a harmonium pan should not be fitted at the back, if your correspondent will sacrifice the sub-bass. The harmonium reeds will need a good deal of smothering up; but there is no difficulty about that, and the only thing that would be any trouble would be making the double pallet action throughout the register. I presume the sub-bass is worked by the double pallet. The touch would be the same then over all the keyboard. The harmonium pan would be simply inverted where the sub-bass is now, and might be screwed to the soundboard or let into it—sufficient room for a 4in. pallet being all that is required. The "slot" in the soundboard would thus be 4½in. wide, and 33in. long. Leather round edge and secure pan by means of screws and hooks. What would in a harmonium be the well of the pan is thus open to the air; that would be boxed in, and would contain the valves admitting wind to the registers, and the stop-action would be simple. I see no reason why that should not be done; but I do not advise it, for unless the harmonium reeds are filed down they will take an awful lot of wind, and here a prime question comes in—How large are "Beta's" bellows, or can larger be put in the case? Assuming there is no difficulty on that score, the main point is to see that nothing is done to render it difficult to get at the back row of existing reeds. An additional A. O. tubeboard might be planted vertically at the back, or if balance-keys were used, inverted over them (which is, I think, best, as it leaves all clear below for getting at the reeds, and, according to size of case, gives opportunity for producing effects which are not to be had from reeds mounted on one soundboard), as I suggested to "A. H. D.," on p. 501, Vol. XXXII. By the way, it would be interesting to hear how that gentleman is progressing with his instrument; he had harmonium reeds on an exhaust wind. The long keys are not absolutely necessary, if you conclude to use another A. O. tubeboard, for a frame can be made with bent wires to depress the plungers of the additional rows, or push them up, as the case may be; but this frame must be made readily removable, and may be impossible if your stop-action is anywhere else than at the ends of the rows.—Organon.

[46320.]—**Motor.**—In view of the difficulties, I am not sure that a powerful spring would not be best. A weight would need to be either very heavy or to have a fall of many feet. If light, therefore, I hardly think, for a portable machine, that it would answer. I have also thought of compressed air; but would the pumping the air-chamber be inadmissible?—Sunlight.

[46329.]—**Chromate of Calcium.**—To "Analyst."—I would be glad of your information. I want it for battery purposes, and would like to make about 14lb. at a time. It is stated in Sprague's "Electricity" as $CaCrO_4 = 156$.—W. P.

[46368.] — **Clock.** — I once had "Anxious Amateur's" difficulty with an American clock. Try unscrewing the winder the wrong way (apparently)—*i.e.*, to the left instead of right. In my case this unfastened the winder; the hand-setter is held on by friction only; pull straight and hard, and it will probably come off.—Calne.

[46381.]—**Three-Legged Gravity Escapement.**—To "Alfojoe."—I send a sketch and description of a three-legged gravity escapement, which is almost a literal transcript from a book on clocks, by J. W. Benson. This illustration represents a regulator-escapement as it would appear in a front view; the pallets are lifted by the three central pins. The locking-teeth vary in size, from 1in. to nearly 2in. The horizontal pieces projecting from the top of the pallets form the adjustment for the arc of the pendulum. The great advantages possessed by this escapement over all other gravity-escapements, &c., are as follows:—1. It requires no oil. 2. The angle of the detent-planes reduces the friction to almost nil. 3. As the impulse and the unlocking are in one direction, the escapement is unlocked without recoil of the impulse arms. 4. No impending force to the pendulum from inertia of impulse-arms. 5. The hold in the stops can be increased or diminished to any practical extent by reason of the inverted impulse-arms. 6. Less affected by any disturbing forces of the train in proportion to the pressure on the stops. 7. Will bear more weight and give more power to the train without increasing the arc of oscillation. 8. No possibility of tripping under any increase of motive power. 9. The minimum arc of vibration to unlock is eight-tenths of a degree. Other escapements of similar construction require from 4 to 7°. 10. Take less weight for the motive power in proportion to the difference of pressure and draw on the lockings. 11. Is unlocked by gravitation, instead of by the pendulum, and at the time of impulse. 12. Requires neither fly nor remontoire, and so reduces the weight of the motive power by about half. 13. The impulse giving motion to the pendulum increases as the force of gravity on the pendulum decreases. A great advantage over those escapements in which the unlocking is done by the pendulum when its momentum is nearly expended, and at the extremity of its arc of vibration. 14. The angle of the detent-planes can be set so as not only to offer no resistance to the unlocking, but to give an actual impulse in the same manner as the impulse pallets of a dead-beat escapement. This completely frees the impulse which gives motion to the pendulum from any retarding influence of the train. 15. The arc of vibration is more equal in this than in any other gravity escapement. 16. It is not so liable to stop in consequence of a diminution of arc from the variation of motive force in the train. 17. It will answer for regulators as well as for turret clocks, its arc of vibration being from 1° to 3°. There is another form of this escapement called the double three-legged escapement. In general principle, it is much the same as the single. There is this difference: that there are two locking-wheels, acting on opposite sides of the pendulum, with one pallet only on each side, so that the locking-wheels act alternately. There are several minor advantages claimed for this form of escapement, which I need not enumerate here, as it is beside the question. Explanation of reference letters in illustration:—A, support cross-bar; B, suspension spring; C, pendulum rod (portion); D, frame (adjustable); E, pallets; F, three-legged locking-wheel; G, impulse arms; H, rod extension; I, adjusting screws; J, rod extension; arrows indicate present motion.—Alfojoe.

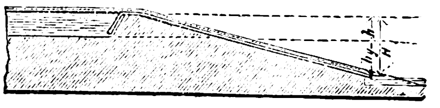


[46422.]—**Organ.**—You simply require another beam, with splayed backfalls under your present one, and made to rise and fall. The second beam must, of course, be splayed to the octave. It may be attached to the key by a second sticker, or, if you have not room for that, by a block on the present one. Mind that the coupler only pulls down the pallet, and not the key, or else it will play all the octaves up the keyboard.—Journeyman Organ Builder.

[46433.]—**Potato Disease.**—As an Irishman who is now putting down his thirty-second crop of potatoes, I hope I may venture to supplement Mr. Adam's answer, which is quite correct as far as it goes. I open my drills from 28in. to 30in. wide, according to kind of potatoes—thirty for Champions. I put the farmyard manure in the drill and lay the potatoes, or cut setts on it, then, when the plough has gone one way and half-closed the drill, I have the mixed kainit and other artificial manure spread along; it thus does not come in actual contact with the potatoes, and when the plough comes back on the other side and finishes the drill, it is mixed in the earth in the middle of the drill. It is a very general practice to put the potatoes under the farm-yard manure, but I find it better to put them over if the drills are made large enough and opened deep. I find nitrophosphate (Hill's) much better for potatoes than any superphosphate, and now always use it mixed with the kainit. I also found phospho-guano, if good, better than superphosphate, compared by money value, of course. Well rotted manure certainly is the best for any crop, and bulk for bulk, of course, is much more valuable than fresh made; but if a corresponding quantity of the latter is given to them, I have no hesitation in saying that there is no crop in either field or garden in which it makes so little difference to have the farmyard manure well rotted as potatoes, and I know many experienced farmers who say that if they really get a corresponding quantity of it they will be actually better on fresh-made manure, but the bulk of farmyard manure reduces so much in rotting that well-rotted manure is always apt to be given really more liberally than the other. Of course, in speaking of fresh-made manure, I mean that it should be properly made under cattle, made up in a compact solid heap, or better still, pit, and not left exposed to wind and weather; if the weather, while it is being made, is very dry, it should be moistened with water from a barrel or water-cart, and never be let get dry. Loose, dry, unrotted sops, put into a drill, are of course nearly valueless.—G. J. H.

[46437.]—**Soda-Lime.**—If the soda-lime is required for the determination of nitrogen in manures, &c., the following method may be employed:—Take equal weights of slaked lime and Na_2CO_3, and mix well. When it is required for use, heat sufficient in a porcelain basin, and allow to cool. When heated with this, nitrogenous substances give up all their nitrogen in the form of ammonia. The substance is so readily prepared that it is best not to attempt to use it again. "Agricola" will find full directions for analysis of soot in Fresenius's "Quantitative Analysis." Before choosing a balance he had better get catalogues from good dealers (Jas. Wooley, of Manchester; Townsend and Mercer, Bishopsgate-street, London, &c.—Magnus.

[46449.]—**Underground Siphon.**—To give the discharge of water by a siphon, it is necessary to know the differences of level between the surface of the water in the pond that has to be drawn from and the discharging orifice of siphon pipe. Supposing the pond to have a continuous supply of water, and equal to that discharged by the siphon, the level will then be constant. But if the pond has to be drained, the levels will vary; so will the quantity discharged vary. Now, if the descending pipe has a length of 300ft., and an inclination of 1 in 4, the horizontal distance will be 291·60ft., and the vertical fall 72·90ft. By my formula a pipe of 2in. bore, at an inclination of 1 in 4 (long pipe), will discharge at a velocity of 586ft. per minute, and a 2in. bore pipe contains approx. ·133 gals. in a foot of its length. Therefore, the discharge in gals. is 77·938 per minute.

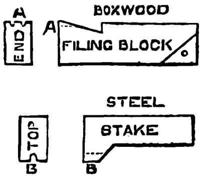


v = velocity of flow in feet per minute.
d = diameter of bore of pipe, in inches.
R = ratio of inclination = $\frac{L}{H}$

$$v = \sqrt{\frac{690{,}000 \cdot \times d}{R}}$$

I checked off my figures by "Box's" formula, and made it 75·342 gals. per minute, a difference of about 2·50 gals. per minute. I will leave it to you and others to say which is right. There is one other matter to be considered; that is, the length of the ascending pipe from bottom of pond to the top of siphon; this cannot, in any case, exceed 34ft., vertical height. The inlet aperture or mouth should be made as near as possible the true "vena contracta," so that the entering water may flow therein with as little friction as possible and unimpeded. The friction of the water, in passing through the ascending pipe, will, to a certain extent, retard the flow in the descending pipe.—Tubal Kain.

[46457.]—**Jewellery Repairing.**—To remove old rivets from brooch-joints, file off burr from small end, place large end on tool (illustrated below), with pin over groove, B, and drive out with punch or joint-pusher and hammer. Holes in new pins are opened by means of joint broaches, to be bought at any jewellery material dealer's. Repointing is managed by placing pin in pin-tongs or hand-vice, and filing same whilst revolving towards you in a groove, A, of filing block (shown below). Hard soldering is much to be preferred to soft soldering in almost every case, but soft soldering is quicker and the articles require less cleaning after. To hard solder, clean the parts to be joined, also solder; place on a piece of charcoal, cover joint and solder with powdered borax and water mixed to a paste. Heat with spirit-lamp and blowpipe (not blowing too hard at first), until solder has run evenly to every part required; when set, dip in water to remove superfluous borax, which would otherwise cause some trouble in removing. The silver solder you had better buy ready for use. Joints and catches you can buy in great variety to suit different purposes at the material dealer's. Any other information will be gladly given by—C. M. R.



[46460.]—**Tortoiseshell.**—If the tortoise is buried in the earth for about two months and then taken out and cleaned, all the soft parts of the body will come away readily. A brother-in-law of mine has repeatedly adopted this plan with success. The shell may be polished by any of the modes in use among horn or bone polishers. All loose epidermis must be removed, and rough uneven parts rubbed down or scraped. Finish off with fine sandpaper, followed by rottenstone and oil, with plenty of friction.—Alfojoe.

[46463.]—**White-Lead.**—I am afraid that Hugh Tunnadine has fallen into error in his answer to this query (p.111). He says: "If, on the addition of a small quantity of sulphuric acid to some of the white-lead you perceive effervescence, you may be sure it contains something which ought to be absent." So far from this being the case, one may be sure that if the addition of a small quantity of sulphuric acid to a sample of "white-lead" produces no effervescence, there is something absent which ought to be present, namely—white-lead itself. The substance in question, when in its pure state, is a hydrated carbonate of lead; but as met with in commerce, it is commonly adulterated (and often, to a large extent) with sulphate of barium, sulphate of lead, lime, and chalk. There is no simple "rule of thumb" method of testing the purity of white-lead; but if "Creta" has the means of performing an analysis, I will tell him how to proceed on his inserting another query.—Alfred W. Soward.

[46465.]—**Midland Bogie-Carriages.**—The longest bogie-carriages are 54ft. in length between ends of frame. In 1876 the company possessed 68 bogie-carriages—25 Pullman drawing-room cars, 11 Pullman sleeping cars, and 32 bogie carriages—all of which are carried upon two 4-wheeled bogies. The working of these was found so satisfactory that a number of 6-wheeled bogie-carriages were ordered. These are the largest yet constructed. I give a few dimensions, since they may interest some of your readers:—

	Ft.	In.
Total length of frame	54	0
Width over panels	8	0
Width outside steps	8	6
Width of bogie frame	6	6
Distance from centre to centre of bogies..	36	0
Wheel-base of each bogie	10	6
Dia. of bogie-wheels	3	7

Three first-class compartments to hold 18 passengers, four third-class compartments to hold 40 passengers, and one luggage compartment. The centre of the roof is raised above the level of the outside and fitted with glass panes, affording additional light and ventilation. The latest carriages, however (1878-1881), are four-wheeled bogies without the raised roof, all built at Derby. The Scottish Joint Stock (M.S.J.S) possess 30 bogie-carriages (10 six-wheeled and 20 four-wheeled bogies). The six-wheeled bogies have not the raised roof.—Meteor.

[46481.]—**Boiler-Pump.**—I am much obliged to "Was-Heil" for his information, but he does not go far enough. He says I shall require to find how full the pump is at each stroke. I should esteem it a favour if he would tell me how to find this.—Slocum Podger.

[46489.]—**Bicycle-Making.**—I beg to tender my thanks to "Sunlight" for his answer to the above, and in reply to his question as to what parts I want information on, I venture to ask him for a few hints on the fitting of wheels; as, according to his opinion, I have not gone the right way about it. Having purchased everything except bearings in the rough, the hubs not being drilled, would it be possible to drill them in a lathe, and if so, what will be the best way to hold them to insure the holes being at the right angle? In fitting neck in backbone, I have made a fair fit, but find that the centre is not at its right angle, as, when it is adjusted in head, the back wheel will be some 6in. behind front. To remedy this I shall have to file neck to fit at a different angle in backbone, in which case it will fit rather loosely. Will brazing hold it sufficiently, or will it require pin? I would rather do without pin, if possible. I may mention that I do not intend to do the brazing myself, but to get it done by a practical man.—An Amateur.

[46493.]—**Lathe.**—Do you mean to cut off square bars, or to turn them? Have you a lathe already, or do you wish for sizes, &c.? as I fail to quite grasp your meaning. The size of back-gear would depend on the size of the head-stock, and the size and weight of fly-wheel and the height of centres. Would a 4½in. or 5in. centre lathe suit you?—Sunlight.

[46497.]—**Fortified English Cities.**—Taunton, Tiverton, Exeter, and Barnstaple were at one time entirely surrounded by walls, and stood sieges in Cromwell's time. The time of dismantling cannot be fixed, as they fell into decay and were removed bit by bit. The walls of that unique city, Chester, are still standing, and it forms a pleasant walk on the top of them around the old portion of the city. —Working Tom.

[46498.]—**Cement for Glass.**—Use Canada balsam, which can be obtained at any artist's colourman. This is used by opticians to cement their lenses together, and is perfectly transparent. —Peganredstuff.

[46498.]—**Cement for Glass.**—Try Canada balsam or clear glue (gelatine), to which has been added a small quantity of bichromate of potash. The latter soon loses its yellow tint, and becomes unaffected by damp when exposed to daylight.—W. T. B.

[46498.]—**Cement for Glass.**—I should advise as the cheapest and easiest made the following:—2 parts common black pitch and 1 part guttapercha, melted and worked together till mixed; or two parts shellac, 1 part Venice turpentine, melted together. These would want using warm. They are both impervious to weather influences. Marine glue would also effect your purpose, though more expensive—recipes for which you will find in back numbers.—Fellow Workman.

[46499.]—**Lathe.**—The proper and only way to fix the wheel on the crank-shaft is to get the wheel bored out so that it will just slip on the shaft. If the shaft be a square one, then my advice is to get a collar shrunk on the square shaft. Have this turned down and the wheel-boss bored to fit it. Then cut a keyway in the wheel-boss, and a keybed on the shaft. The shaft itself may run in either centres or bearing; but you should see if it is made to run in centres; if so, the ends will have a piece of steel welded in, and a countersunk hole in it for the centre. The shaft end and centre must both be dead hard. If your shaft has not centre ends already fitted, I should prefer to run it in bearings, and for these antifraction metal is very good.—Sunlight.

[46501.]—**Exposure of Gelatine Plates or Films.**—"Beginner" must measure the aperture of lock of his stops and square their diameters. The products will give their relative speed, thus: suppose the full aperture to be 6-8in. the No. 5 stop to be ⅝in., and the No. 1 2-8in. in aperture. The relative speed will be calculated thus: 6 × 6 = 36, 5 × 5 = 25, 2 × 2 = 4. No. 1 will take nine times the exposure of the full aperture, No. 5 one-third longer. "Beginner" will find in my "Filmographic Manual" a number of suggestions regarding exposures on different subjects, which are of value to beginners.—A. Pumphrey.

[46503.]—**Jamming of Tapered Journals.**—The taper shown by "Glatton's" diagram is far more than I used in lathe-mandrels when manufacturing such. The angle should be as small as possible, because the larger diameter wears soonest, and in order to prevent the sticking of the cone, a shoulder is provided.—J. J. A., Liverpool.

[46504.]—**Air and Steam.**—If two vessels are filled, one with steam and the other with air, both heated up to 248° Fahr., or the pressure of two atmospheres, and connected by a tube fitted with air-tight cocks, and the communication between the two vessels opened, supposing that no heat is lost by radiation, the pressure in the vessels will remain the same as before the communication was opened. Secondly. If there is no loss of heat, there will be no condensation of steam. Thirdly. If the mixture of hot-air and steam at 248° Fahr. was compressed to say one-third of its volume, there would be no condensation, supposing there was no loss of heat; that is to say, if you keep a regular heat your steam stands at the same pressure, and if your steam stands at the same pressure, it is an impossibility for it to condense, because, as your steam begins to condense so the pressure begins to decrease.—Snowball.

[46507.]—**Wax.**—Paraffin wax is colourless, and will not damage the most delicate colours; but it is doubtful if wax is better than a flexible varnish for a fabric.—W. T. B.

[46509.]—**Analysis of Soils.**—"High Farmer" should procure Church's "Laboratory Guide," published by John Van Voorst, Paternoster-row. It contains a vast amount of information on analysis of manures, soils, and agricultural products; but, as an amateur in agricultural chemistry, I often find the processes too condensed to be easily understood without a teacher. With its assistance I have of late made considerable progress in "agricultural analysis," and can safely recommend it to "High Farmer" as a trustworthy guide. Whilst on soils, allow me to ask if any of "ours" can inform me where I can obtain an account of Professor Way's researches on the retentive power of soils, and how he produced artificially the double silicates of alumina and soda, alumina and lime, &c. I have, during the past winter, been experimenting on the power of soils to hold soluble phosphates, and found that a quantity of water equal to a rainfall of about 5in. washed out within 1 per cent. all the soluble phosphates added to the soil. In one case I obtained 12 per cent. more of monocalcic phosphate than I added. The soil, in this instance, contained naturally 3 per cent. of calcic phosphate. In carrying out these investigations, I filled a large-sized flower-pot with soil, placed the manure on the surface, added rainwater in small quantities at a time, and collected the drainage in a beaker placed below the pot. Can any of our chemists give me the results of similar experiments?—Agricola.

[46510.]—**Photography.**—The simplest, cheapest, and most reliable means to change dry-plates in the field is an opaque bag, with sleeves and indiarubber bands to pass over wrists, and two non-actinic apertures opposite each other, through one of which can be seen the necessary operations. The bag occupies little space, is light, and useful for many purposes besides that for which it is specially designed. All changing-boxes are expensive, liable to get out of order, and are a constant source of trouble and vexation. Hare's is the best.—W. T. B.

[46510.]—**Photography.**—Perhaps the plan I use, with complete satisfaction, instead of a changing-box, might suit "F. C." It is a bag of thickest black calico doubled. The front and bottom are kept rigid by cardboard. When not in use it collapses and occupies little space. There is a sleeve at each end wide enough to admit dark slide, box of plates, and my arm. Elastic bands round the ends of the sleeves keep them tight to my arms and effectually exclude light. There is a tape band at the top which goes round my neck, and the bag hangs level with my elbows. As I have to manipulate by touch, the backs of the plates are marked before going out, by gumming to each a small piece of paper, which is easily felt by the finger. With this I am able to change any number of plates when out for a day. The whole thing cost me about two shillings. If "F. C." wishes, I shall be happy to give further particulars as to shape, dimensions, &c.—W. H. S. W.

[46511.]—**Yellow Stains and Tin Dishes.**—Where the yellow stains do not arise from faulty plates, they can be removed by soaking in a saturated solution of alum, with two ounces citric acid added to each pint. A yellow stain sometimes is produced by allowing white light to fall on the negative before it is quite "fixed." Tin dishes well coated with black varnish may be used for development.—W. T. B.

[46511.]—**Stains on Gelatine Films.**—The dark colour of your negatives is most likely the result of continuing the action of the developer too long, possibly owing to the exposure having been too short; or the stains may have come, as often do, by washing between development and insertion in the hyposulphite solution: pass direct from the former to the latter to avoid the chance of stains. Tin developing dishes are quite as good as any other material; for the alkaline or iron development of gelatine negatives I have used them exclusively for twelve months.—A. Pumphrey.

[46516.]—**Caledonian Engines.**—The classes "Netherby" asks about are:—(1) 1 to 29, 6ft. coupled, cylinders 17 by 22. This lot comprises several sets which vary in date. Builders, Dübs and Neilson. (2) 30 to 41: Neilson, 1872, 7ft. coupled, cylinders 17 by 24. (3) 42 to 48; Dübs, 1874, 7ft. coupled, 17½ by 24. (5) 49 to 58: 6ft. coupled, Neilson, 1874, cylinders 17 by 22. (6) 59 to 64: 6ft. coupled, Jones and Potts, 1850, cylinders 15½ by 20; (7) 65 to 75 (originally to 76; 76, however, blew up at Carlisle, and was replaced by the first of the 8-footers in December, 1859): 7ft. singles, cylinders 16 by 20 (originally 15½ by 20), Greenock, 1855; (8) 76 to 87: date from 1859 to about 1864: 8ft singles, cylinders 17 by 24. (9) 88 to 91: St. Rollox, 7ft. singles, cylinders 17 by 22; built as main-line engines, but replaced in 1875 by the new 8-footers 113 to 116, now stationed at Carstairs. (92 to 97, and 103 to 107: Already described, vide last vol.)

98 to 102, and 108 to 112: 7ft. coupled, St. Rollox, 1867-8, cylinders 17 by 24; 113 to 116: 8ft. singles, St. Rollox, 1875, cylinders 17½ by 24; 117 to 122; 7ft. coupled, Neilson, 1868, cylinders 17 by 24; 123, 124: 7ft. coupled, Crewe type, Perth, 1869, cylinders about 17 by 22; 125 to 129: Bogie Express, 7ft. coupled, Neilson, 1877, cylinders 18 by 24; 130 to 139: 6ft. coupled, Dübs, cylinders 17 by 22; 294 to 299, and 306 to 309: 6ft. singles, cylinders 16 by 20, Perth, S.C.Ry.Co.; 300 to 305: same, but have no domes, Sharp Stewart, Manchester; 311: now broken up; was a Crampton engine, with 7ft. wheels, and cylinders 16 by 20, and belonged to the S.N.E.Ry.; 312 to 319: 7ft. singles (originally S.N.E.R.): built Vulcan Foundry Works, Warrington, 1866, cylinders 16½ to 17 by 22; 310: 7ft. single, similar to 88 class, by Barclay, Kilmarnock. These dates are the original, not rebuilt, dates. The number of tubes varies very much even in engines of the same classes. 88 to 91 class have from 144 to 160; 312 to 319 have from 150 to 202; 294 about 228; No. 305 about 188 tubes. I write this, because, when writing letter 19042, I did not think that they would vary to such an extent. A great many of 65—75 are scrapped. Yes, "Netherby" is quite right with regard to the old Greenock-built singles; their stroke was only 20in. As he asks for a description of them I will endeavour to gratify him. I inclose a rough sketch of one of those built by Taylor, Warrington (Nos. 10 to 15), the dimensions of which are as follows:—Cylinders, 15in. by 20in., stroke placed 6ft. centre to centre; steam ports, 1¼in by 10in.; exhaust ports, 3in. by 10in.; boiler barrel, 3ft. 6¾in. diam., 9ft 9in. long; tubes, 158, 1¾in. diam., and 10ft. 1½in. long; inside firebox, 3ft. long, 3ft. 6in. broad, 3ft. 8in. deep; carrying-wheels, 3ft. 6in.; driving-wheels, 6ft.; safety-valves, two, 2½in. diam., graduated to 90lb. pressure per sq. in.; extreme bearing, 12ft. 0⅝in.; rail to top of chimney, 13ft. 6in.

	Tons.	Cwt.
Wright (in working order) on leading-wheels	5	15
Weight (in working order) on driving-wheels	9	15
Weight (in working order) on trailing-wheels	3	10
Total	19	0

I will simply give the leading dimensions of some other classes. Nos. 33 to 38, 6ft. coupled; cylinders, 15in. by 20in.; Nos. 2 and 16 (afterwards 77 and 78) "Bloomers," cylinders, 9in. by 15in.; leading and trailing-wheels, 3ft. 1in.; driving-wheels, 5ft. 1in.; working pressure, 200lb. per sq. in. Older classes still belonging originally to the Glasgow, Paisley and Greenock, and also the Gamkirk Railway were then in use. Some of the former had 12in., other 13in. cylinders, and 18in. stroke, single driving-wheels 5ft. dia.; the cylinders were inside. The fastest train run by the old 6ft. singles was timed at over 51 miles per hour. That was from Edinburgh to Carstairs, 27 miles 37 chains, in 32 minutes. They however, seldom ran to time with that train, notwithstanding that it rarely exceeded 4 vehicles, or 22 tons, and was much oftener less. The line referred to is a very heavy one, the first 18 miles 33 chains being a continuous rise, including gradients 1 in 100, 1 in 115, 1 in 120, and even steeper, and the remainder, which falls towards Carstairs, is quite as steep. The express from Glasgow to Carlisle in 1849 was allowed 2 hours 40 minutes running home, five stoppages. The following was its running:—

	Miles.	Min.	Speed.
Glasgow, south side to Gushet Junction	—	2	—
Gushet Junction to Motherwell	12	20	32·7 m.p.h.
Motherwell to Carstairs ..	15	28	33·21 ,,
Carstairs to Beattock	34	52	39·23 ,,
Beattock to Lockerbie	14	20	42·0 ,,
Lockerbie to Carlisle	26	38	41·05 ,,

Coke consumed on this run with 7 carriages was from 11 to 14 cwt., according to the state of rails. In 1850 the 10.30 a.m. express was allowed 3 hours 22 minutes, five stoppages included, to run from Glasgow, Buchanan-street, to Carlisle, 105 miles, a little slower. If I have not given the dimensions fully enough that can be easily remedied.—Carstairs.

[46520.]—**Gas-Engine for Launch.**—It has been already tried. See remarks I made on the first attempt about 1½ year since. Subsequently a great improvement has been made. Now such an engine could be made that would be quite equal to a steam-engine. The chief difficulty is that of handling the boat, or, in other words, to manage the reversing, &c. The first launch had an arrangement fitted to it, so that by the action of one lever the screw-shaft was made to run, so that the boat went ahead or astern, or the shaft ceased to revolve altogether. But this was attended with several drawbacks: one was that, supposing the engine was driving the boat ahead, and it became needful to promptly reverse, it could not be done instantaneously, as although the screw-shaft would stop, still, the engine had to be slowed down, or the clutches would be likely to be smashed, as the shock due to suddenly coupling the shaft and fan, which would be at rest, or nearly so, with the engine perhaps going some 120 a minute, would be very great; therefore, it becomes imperative to slow the engines down to, say, a moderate speed. Recently, I have evolved the theory of a reversing-engine, so that the engine and shaft would be rigidly connected, except when the boat was stopped for a short time for any purpose; but that involves the application of an air-pump and chamber. Where the starting and stopping are not likely to be wanted at a moment's notice, then the first plan is far best, as the engines are always running and making their gas. As yet I have not given the question the time and thought I should like; but, suffice to say, that a gas-engine can be applied to a launch without difficulty, so long as momentarily stopping and starting is not needed. The gas-making arrangement is perfect, and water for the cylinder jacket would be, of course, drawn from the sea. There is one point that I would like, in fairness, to mention—viz., that the engine would be larger and heavier than a steam-engine of the same size. Against this fact we must, in equal fairness, mention the gain of weight due to no boiler being needed, and the space also gained from the same cause. I am fully certain that a little time will show the application of gas-power to marine propulsion on a small scale, and I believe I was the first who applied a gas-engine to such a purpose.—Sunlight.

[46530.]—**Rotary Water Motor.**—You would not get an economical rotary motor, neither could you get enough power without far more water than a ¾ pipe would convey. The only motor that would be economical of water, and yet give you the required power, would be either a "Haigh" or a "Megy," both of these being reciprocating forms utilising the full pressure of the water. The rotary forms do not do this, and, unless you can get permission to make a copy of one of the well-known reciprocating motors, I quite fail to see how you will attain your desired end. I would gladly help you in the matter; but have you, for instance, the necessary tools to construct a motor with, if you even had the necessary plans?—Sunlight.

[46531.]—**Yacht-Deck.**—I should consider yellow pine very good, as it is light, durable, and good in appearance if properly got up. As to width, I should advise 4in. well spiked down.—Sunlight.

[46531.]—**Yacht-Deck.**—Use yellow pine, as you have been advised; pitch-pine not so suitable, too heavy, hard to work. Size of planks about 6in. by 1in., edges to be grooved to take a loose tongue, put in with white-lead. The deck beams to be securely fastened to the hull timbers. To fasten the deck-planks, bore with a bit a flat button-hole, say ½in. deep, ¾in. dia., then drive in spike and fill up hole with a wooden plug; ¾in. good dia. turned edgeway of grain, dipped in thick white-lead paint, and plane deck all even when laid; but ends and places where likely to leak caulk in ordinary way. "Yachtsman" cannot do better than to get a shipwright apprentice to give him a hint or two on the spot.—Working Tom.

[46536.]—**Shaft.**—Do you mean that the pulley on the new shaft is out of the vertical line 30in.? If so, you will have trouble, and the strap is likely to keep slipping off. With pulleys with much rounding it might, with a light load in proportion to the transmitting power of the strap, keep on. But it would be a most unsatisfactory plan.—Sunlight.

[46536.]—**Shaft.**—Shaft will work properly with an open belt, the way "G. O. W." wants his shaft to run, and he can determine the exact position of the pulleys before fixing, by making a drawing to scale, say ¼ full size, and taking care when the belt leaves one pulley it makes direct to the face of the other pulley, and when it leaves the driven pulley it must be in such a line as to go direct to the driving-pulley. Note—there is only one place and position to fix the pulley, to keep the strap on; no guide-pulleys required. Let "G. O. W." prepare two pulleys of the size he requires ready for fixing. Fix up his shaft and put on his pulleys, but not as yet cut any key-ways on the shafts. Let him put the band on, having just tightened the pulleys, his shafts running empty for easy working; and if the strap does not keep on, send sketch to show which way he wants the shafts to run, and size of pulleys; if the strap keeps on, cut key-ways on shafts and tighten up.—Working Tom.

[46538.]—**Utilising Water Power.**—To "Sunlight" and Others.—I am sorry to say that I cannot hold out much hopes to this querist. The power is but the weight of the water multiplied by the vertical height, but less pipe friction also. A gallon of water is calculated at 10lb., therefore the gross power would be 1,050 pounds per minute. Deduct from this first friction of the length of small pipe, and then the loss due to the motor, and there is very little left. Motors of the class mentioned must be good to yield 60 per cent. useful effect, and most generally they range from 45 to 50 per cent. only. Allowing that a first-class one is used, but about 1-50th of a horse-power is obtainable, if we make no allowance for friction. The utmost, I believe you could possibly get, would be an available power equal to about 400 foot-pounds per minute.—Sunlight.

[46541.]—**Ants.**—Pour ordinary paraffin oil into the ants' nests and about their haunts. This will kill all there and disgust their visitors.—W. T. B.

[46542.]—**Broken Steam-Gauge.**—To "Sunlight" and "Jack of All Trades."—You may perhaps patch up your gauge with soft solder applied with a soldering-iron; but be careful to apply only sufficient heat to run the solder. Do not heat the tube more than necessary; then clean off the excess of solder, when the joint should show no sign of a line, which would be the case if the crack was not entirely filled up. A mercury gauge is easy to make, whether for pressure or vacuum. For which purpose do you require it? If for pressure, except for 20 or 30 pounds or so, it is a very cumbrous form of indicator. On hearing for which purpose you want it, I will, with pleasure, send you sketch of an approved and recent form of instrument.—Sunlight.

[46548.]—**Coned v. Grooved Pulleys.**—I take it your query should have been "Flat v. Grooved" pulleys; as such I will answer it. A grooved pulley transmits power for small purposes far better than a flat one, and as the strap does not need to be so tight, there is far less side strain. But to transmit large powers the sectional area and surface could not be increased to suit except at a great cost. There is another drawback with the grooved pulley also, and that is its inadaptability to be used with fast and loose pulleys. And it cannot be shifted from one groove to the other. A V-grooved pulley should have a V-shaped strap, the point being taken off, so that it cannot bend at the bottom. I have several of these in use doing far better than the round strap in the V-groove. I believe in this journal it was recommended to use a round section groove with the round belt. But that I take to be an error. Unless the belt fits the round of the pulley tightly, it does not transmit its power properly, and as it stretches in use its diameter gets less, and hence it drives on the bottom side only. A V-pulley and strap of same section does not get a bad fit by wear, as it wears equally downward, and it takes great wear to reach the bottom of the groove, and until it does the belt drives full power. I do not so much advocate the round belt in the V-pulley, as the surfaces in contact are not so ample. But a V-belt will transmit power better than any other form for small work.—Sunlight.

[46550.]—**Instantaneous Photography.**—All really good very rapid gelatine plates by reliable makers are sufficiently sensitive to be impressed by the exposure of 1-100th of a second. The labels attached to parcels of plates are often very misleading, and no makers' plates are always alike. Use a quick-acting lens of short focus, and alkaline developer, with a minimum of pyro and as much ammonia as the particular sample of plate will bear without fog; develop in a very subdued light. —W. T. B.

[46550.]—**Instantaneous Photography.**—There is a lot of nonsense talked about this class of work; every subject cannot be taken instantly at any time. If you have rapid gelatine preparations and you do not get your pictures quick enough, you may do a little by increasing the amount of ammonia in your developer, or even wetting the picture front with an ammoniacal solution. If this will not give you the speed desired, use a larger aperture to your lens. If that is not enough, use lenses of shorter focus, take small negatives and enlarge the positives from them.—A. Pumphrey.

[46555.]—**Induction Coil.**—The dimensions of primary given are about the same as in my coil which gives 8in. spark for about $5\frac{1}{2}$ miles of No. 36 wire. As you appear to have about 10 miles on, I think you should get a longer spark, though it is possible, as the wire is so fine, that the smaller quantity of electricity passing becomes dissipated in the brush discharge without forming a spark. I think it would have been better to have confined the secondary to about 6in. or 7in. of the middle of the primary, as the inductive effect there is much greater than near the ends. However, before doing anything more I should try a mercury-break. Put the present break out of action and join a thick platinum-tipped wire to the spring. Connect the contact-screw to a small quantity of mercury in a beaker, or other deep vessel, and cover with an inch or two of spirits of wine. If, on making and breaking the circuit by the platinum-tipped wire at the mercury surface you get a better spark, a permanent mercury break can be arranged, as in the description of my coil in No. 779. See also Nos. 782, 93, 97 for further particulars of coil. I have never succeeded with the platinum-brake, though others appear to make it answer.—J. Brown, Belfast.

[46555.]—**Induction Coil.**—A coil of your dimensions will require quart-sized Groves to get full effects.—J. F. Hewitt.

[46562.]—**Drying Gelatine Emulsion-Plates.**—I should recommend "J. G." to use a paraffin oil-stove, the combustion of which does not in any way injure gelatine-plates; and as to ventilation, a chimney let into the roof and provided with a cap to keep out light and wet would probably answer every purpose.—W. Robinson, jun.

[46563.]—**Washing Photographs.**—A siphon-trough, with sufficient pressure of water to keep the prints in constant motion, answers admirably, and will effectually wash them in two or three hours, provided the apparatus is not over-crowded.—W. Robinson, jun.

[46563.]—**Washing Photographs.**—If you refer to recent back numbers, you will find I described two forms of automatic photo. washers. One is a rotary one, actuated by the water supply itself, the other by a small bucket-wheel. Either of these would meet your requirement. And if you propose to be your own constructor, I shall be happy to furnish any further details you may find needful.—Sunlight.

[46564.]—**Organ.**—The front pipes of an organ should be of metal, if they are intended to speak. They should be of 8ft. pitch, open diapason, if the soundboard is constructed to receive them. In some small old-fashioned organs the front pipes (if pipes they may be called) are made of wood, in the form of an ordinary metal diapason, and then gilded. Such as these are, of course, only for ornament. In this case, it is rather difficult to advise, apart from a personal examination of the organ in question. It is necessary that the description of the instrument should be more detailed and explicit.—G. Fryer.

[46569.]—**Boiler.**—If yon have room enough, an egg or dish-end boiler, 6ft. by 2ft. would answer very well, with a good-sized grate for burning rubbish. You might be able to buy a good, second-hand one that would stand 10lb. working-pressure. If you haven't the room to spare, go in for a vertical boiler, 5ft. by 2ft. 6in.—Labor Omnia Vincit.

[46569.]—**Boiler.**—With 10lb. steam you could not get 300 a minute with a 3in. cylinder. Where is the friction to be dealt with? The pressure is so low that except under most extraordinary circumstances only could you get near to the speed you name, and a very light load would still further reduce the speed. I fear you are under a misapprehension also on another point, and that is, if the engine is not strong enough to stand over 10lb. steam, it surely would not endure being driven at 300 a minute. Therefore, you must, if the engine will not stand more pressure than 10lb., be mistaken in assuming it was constructed to run at a high speed. You may rely on it, that if it won't stand the pressure it will break down with the speed, even if it were attainable. I would, therefore, ask you what you propose to do, as I really could not help you as the matter stands. The best I can do is to give you dimensions of a boiler that would supply the needed volume of steam. But the speed you will not get, except you can carry more pressure. I am most pleased to help you if it can be done in a practical way.—Sunlight.

[46570.]—**Weight of Metal.**—Find the capacity of the ladle in cubic inches, and then multiply that by the decimal approximate ·263; the product is the weight (about) in pounds. Exact accuracy is not possible by this method, but the error should be but trifling either way. The constant ·263 is for cast iron; ·283 would give steel; ·3037 brass. Will this help you at all?—Sunlight.

[46570.]—**Weight of Metal by Measurement.**—Multiply the cube contents in inches by ·26 for the weight of cast iron in pounds, or use the simple rules given last year in reply to query 42517 in Nos. 825, 828, and 831. For crane ladles, which are always of cylindrical form, these calculations are convenient; but it is somewhat troublesome to find the contents of a hand or wheel-ladle by measurement, if it is like the convenient elliptic pattern which I have in use, or of any irregular shape, and, therefore, the practical method is to lay aside the castings and scrap from the first pouring, and weigh them; or, if it is desirable to know the capacity of a new ladle of this kind, before it has been used, it may be filled with water, and the weight of water multiplied by 7 (the approximate specific gravity of molten iron). I need scarcely add that before applying the water test the ladle must be lined with clay, as thick as the usual coating of loam; and, as the lining is a variable quantity, the capacity of the ladle will vary proportionately.—Oakland.

[46572.]—**Sound in Pipe.**—The noise is pretty certain to arise from condensation and back-suck of the water. If it be so, the remedy is to carry the steam-pipe into the tank with a bend well above the water-level. At the highest point an inlet-valve should be fitted, so that it falls to its seat by gravity. On steam being turned on, it is partly condensed by contact with the water. A vacuum is thus formed, which the valve would at once destroy, and so prevent the existing noise.—Sunlight.

[46574.]—**Photo-Bath.**—Although opinions differ as to the origin of the stains (commonly called "oyster-shell" markings) referred to, generally speaking, I think they will be found to arise from a disordered condition of the nitrate bath, a scum of reduced silver being formed on the surface of the solution, and a portion of which attaches itself to every plate that is dipped. Filtration, taking especial care that the filtering medium is thoroughly clean and free from impurities, will generally cure a new bath, and act as a temporary expedient in the case of an old one; but to effectually cure the latter, it will probably require to be rendered slightly alkaline, and to be "sunned" for a day or two, after which filter and acidify as usual. Endeavour also that as little time as practicable shall elapse between sensitising and development, and place some blotting-paper in the lower corners of the dark slide, to absorb the solution that drains from the plate. In very warm weather, or the nature of the subjects requiring a prolonged exposure, a sheet or two of damp red blotting-paper placed against the back of the plate is also of considerable service.—W. Robinson, jun.

[46585.]—**An Organ Smothered.**—It is evident, from the wording of this query, that "Unhappy Organist" knows the cause of the organ sounding as it does. To effect the cure, you must remove the cause. All that can be done, in such a case, is to remove the instrument to another part of the church where there will be greater *resonant* power, or a greater amount of space for the transmission of the sounds produced from the pipes. This, I believe, is the only cure. Many organs are ruined in tone and power by their being placed in chancels and other parts of the church where there is not sufficient room between the roof and the tops of the pipes. For this reason many organs have been removed from the gallery, and placed in the lower part of the church. The querist would do well if he were to study the science of acoustics.—G. Fryer.

[46591.]—**Adjustable Plane.**—It entirely depends on one or two facts. The first would be what the patentee of the one in the market claims in his patent. If you could tell me that, I could then better answer the question. A second fact is whether you could invent a plane that would do what you require, and yet not enroach on the claim of the patentee's specification. Then there is the question, Is the present plane patented in England, or only in the States. To make a copy of the existing tool, if it be properly protected in England, would be a direct infringement of the patent, and I should strongly advise you not to do so. The best help I could give you is that if you get a copy of the specification (if patented in this country), and submit it to me, I would then advise you whether it was practicable to make another form without infringement.—Sunlight.

[46593.]—**Automatic Musical Instruments.**—There is an organette manufactured which is blown by the feet, just in the same way as an American organ; but the music is produced by the same method as in the Orguinette, only on a much larger scale. This instrument, which may be obtained in London (one of which I have seen and heard) would, no doubt, satisfy the querist, as it is of greater power for the reason explained above. The sheets are stamped out by machinery. Being an American invention, I am unable to furnish a detailed explanation of the machine employed for this purpose.—G. Fryer.

[46594.]—**Heating Water.**—From the scanty particulars given it is not easy to give a satisfactory reply. As far as I understand you, I think you would do better to use the exhaust steam for heating the water. Fix a coil in the tank and turn the exhaust steam into it, and, if it does not interfere with anything else, take the outlet to the most convenient point. If the boiler is fed with cold water, you would save fuel by feeding it with the hot water from tank.—Labor Omnia Vincit.

[46595.]—**Patched Boiler.**—Make the patch to fit well on the plate first; then mix some good, red-lead putty. Put grummets under the heads of your bolts, and if you take sufficient care in putting it on it won't leak. For flanged steam-pipes, if faced, use red-lead; if rough, indiarubber washers.—Labor Omnia Vincit.

[46595.]—**Patched Boiler.**—In the first place, the patch does not fit on the boiler shell properly. This should be seen to in the first instance. I should make the joint with either a thickness of milled sheet-lead or with thin sheet asbestos. The former you can caulk into the joint, and so make it quite steam-tight. The latter on a fairly true joint will not leak. But in any case get the plate and the boiler-shell something like a fit.—Sunlight.

[46595.]—**Patched Boiler.**—"An Amateur" asks what packing should be used under a patch on a boiler? I think if the amateur follows these instructions he will have no more trouble with leakage. First, abandon bolts altogether, and use $\frac{5}{8}$ set-screws, countersink heads; first, drill two holes in patch, countersink nice smooth holes to fit set-screws with countersunk heads, all the better if turned up in lathe; drill two holes in patch, also two holes in boiler. Mind the screws work free in patch. When got nicely to fit, heat the patch red-hot, apply it to the place as quickly as possible, put in the two screws, and screw them up tight; then take a hammer and gently welt up the patch quickly, but not forgetting to screw it up tight. Let it remain till cold. Take off drill-holes every two inches, mark and drill boiler, but mind the screws all work freely in the patch. When fitted, take it off; and for packing, take some white-lead, mix a little red-lead with it to the consistence of soft putty; then take some cast-iron borings, hammer them as fine as possible, then mix with lead, and hammer all to the consistency of stiff putty; rub the boiler with a little oil and spread on the lead, screw on the patch as tight as possible, hammering all round, and when tight caulk round. I think if the amateur follows these instructions, he will have no more trouble with leakage. I put a patch on a firebox of an engine 16 by 10 over twelve months since, and have never seen one drop of water through it yet.—Cambridgeshire Boy.

[46599.]—**Photo. Portrait-Lens.**—Your lens is not properly corrected, or, in other words, it is not achromatic. No separation of the component lenses will achromatise it. You cannot do anything to it that will do any good, except it be sent to an optician to have it corrected. But this is likely to cost more than it is worth.—Sunlight.

[46601.]—**Object-Glasses.**—In reply to "Poor Amateur," I have failed to obtain any improved definition by the insertion of the plano-concave lens recommended by Mr. Arthur Hinde. I purchased it at a London optician's; it was made for me to order. Can Mr. Hinde inform me how I can test it as to its being made of flint glass, as I ordered it to be? A cheap astronomical telescope can be made with a plano-convex lens, 2in. diam., 6ft. focus for object-glass, and an eye-glass plano-convex of $1\frac{1}{4}$in. focus; this will magnify about 50 diameters, and is the highest power this length will bear. It will show Jupiter and his satellites, Saturn's ring, the phases of Venus, and the craters of the moon; but it will not take the whole of the moon's surface into the field at once; the object-glass will require to be stopped down to $1\frac{1}{4}$in. diam. for Jupiter and Saturn, and 1in. only to view Venus. I made one of this class and length some years ago: it answers very well, and I occasionally use it now, especially for looking at Venus. I very much improved it about 12 months since by adopting a compound Huyghenian eyepiece to it; this improved the sharpness of the image, and enlarged the field. The tubes are made of brown paper, similar to a rocket-case; an old cornice pole was used for the core of the larger, and a round ruler for the core of the smaller tubes. For further ideas as to fitting, study the articles on p. 535, English Mechanic, No. 881, contributed by "Aldebaran." The cost of the two lenses should not exceed 3s. 6d. I would not advise a "Poor Amateur" to make a longer one, at any rate to begin with, as if much longer it is so difficult to manage. My stand is made to screw by a pair of small clamps to the top sash of my bedroom window, which gives opportunity to raise and lower it; of course the sash should be wedged to keep it steady.—E. Y. J.

[46602.]—**Pendulum Spring.**—To "Nicholls."—You don't say in your query the make of the watch. If it be a watch like that one you did a few weeks since, you can get the size as before, and you should know about the strength. Hang it on balance and let it be about same strength as the other you put in, if watch be about same size and make. If you like to try the following it will be a little practice for you. Put hair-spring in about the proper size; if too weak or too strong, change it, and so on till you get the right one; but you ought to be able to select one, put it in, and regulate in about an hour comfortably.—NICHOLLS.

[46604.] — **Incandescent Lamps.** — Three quart Bunsens will not work a Swan lamp, which is a thread of carbon inclosed in a vacuum glass bulb; the incandescent lamps that work with three or four Bunsen cells are made with platinum iridium wire alloy, and are little better than platinum wire inclosed in a tube.—J. SUTCLIFFE.

[46604.] — **Incandescent Lamps.** — I have lighted Swan's lamps with batteries several times. With six Grove's cells the filament is just red. 25 to 30 cells are wanted to give a good light with one or two lamps. 50 or 60 cells light six lamps very well, and they give a better light than they usually do with dynamo current, that from the batteries being steadier. If the lamps are to be lighted for some time, it is best not to have all the cells in circuit at first, but to add them by degrees as the battery becomes weaker. By this means the light can be kept very constant for some hours.—JOHN HENRY KNIGHT.

[46606.]—**Back-Gear Headstock.**—First tell me, Have you a single-geared headstock already, and do you wish to convert it into a back-geared one? Or do you wish to make a new back-gear headstock? I would then tell you how to proceed. In the one case it is a question of adaptation—in which case I should want to know the size and length of present cone pulley, and the distance between the bearing inside the headstock, so that I might calculate the size and widths of the wheels that go on the mandrel.—SUNLIGHT.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last A. W. Soward has answered 45892.

AT a recent meeting of the Société d'Encouragement, Paris, M. Dumas in the chair, Colonel Goulier brought forward, in the name of the committee of mechanical art, a new instrument invented by M. Cuvillier for measuring considerable thicknesses correct to 1-100 of a millimetre. It consists of a divided rule with two fingers, one fixed and the other movable. The former is cylindrical and capable of revolving on its axis but eccentrically, the eccentricity being a millimetre. After measuring the thickness of an object within a millimetre by the rule, the cylinder is turned until the piece is held tightly between the two fingers, and the angle through which the cylinder has turned gives the fraction of a millimetre making up the correct dimension.

THE Siemens "regenerative" gas-burner has been adopted for the purposes of lighting Holborn, from the Circus to Gray's-inn-road. In Holborn twenty-four lamps have been erected, the consumption of which ranges between 22ft. and 24ft. of gas per hour, with an average illuminating power per lamp of 130 candles.

QUERIES.

[46607.]—**Fuller's Battery.** — I have had this battery recommended to me as very constant. Will someone kindly describe materials used in making and charging? Is it fumeless—is it suitable for shocking purposes, and experiments with electro-magnets and induction coil.—C. M. R.

[46608.]—**Strength of Battery Current.**— Is there not a simple plan of testing the strength of current when used for shocking by placing a magnetic needle between some coils of insulated wire and marking the amount of deflection on a dial? Is this reliable? If not, can you suggest a simple and reliable plan?—C. M. R.

[46609.]—**Crystals of Sodium Carbonate.**—Can any of your readers inform me how the monohydrated crystals of sodium carbonate are prepared? Is it much used on the large scale? And is the process by which it is manufactured patented? I have seen Lunge's Vol. II., p. 276, on this subject.—W.

[46610.]—**Rheumatism.**—Will Dr. Edmunds kindly give the querist an opinion as to the benefit, or otherwise, of vegetarianism for a woman of 30 years of age, who is afflicted with rheumatism, but has never had rheumatic fever? And whether the use of the portable Turkish bath is calculated to eradicate this disease? The patient has taken a course of salicylate of soda—with apparently little benefit.—HUM.

[46611.] — **Tombstones.** — Would "Jack of All Trades" be kind enough to let me know what kind of black cement is used for filling in the letters on tombstones, and how to apply it?—DAVID MCKAY.

[46612.]—**N.L.R. Engines.**—To "METEOR."—I want dimensions and sketch of the newest type of the above locomotives, of inside and outside-cylinder types, having a cab in place of a mere weatherboard, and being also, I believe, of somewhat larger dimensions than the old ones. I have seen the sketch in Vol. X. of the "E. M.," but it is not what I want—being one of the old style.—E. E. R. TRATMAN.

[46613.]—**Organ.**— 1. Will Mr. Dresser kindly say what description of felt he uses for pallets, and how thick it should be? 2. Is the windbar fixed into the ends of the wind-chest and on to the soundboard bars with glue in addition to screws? 3. I wish to make of wood pipes the bass octave of the smallest of the three Open Diapasons, for which Mr. Dresser has supplied scales, and the CC of which measured 5½ dia. What scale shall I use in wood? 4. What kinds of wheel-runners are best for an organ of 8 stops—metal or wood—and how fixed?—W. C.

[46614.]—**Tricycle.**—To "SUNLIGHT."—What is the reason that tricycle cranks are all made direct angles? Would it not be better to set them at right angles or triangles? If made the latter, they would always start without assistance. Would they require a balance-weight if made at triangles?—EX.

[46615.]—**Western of France Railway.**—Can Mr. Gobert, Mr. Clements, or other correspondent, favour me with sketch and detailed dimensions of the express engines, with tender, which run on the Chemin de Fer de l'Ouest from Dieppe to the St. Lazare station, Paris, and also ditto of the Chemin de Fer du Nord?—E. E. R. TRATMAN.

[46616.]—**Leclanche Battery.**—Having purchased three improved Leclanché cells (without porous pots) and connected them as directed, zinc to carbon, I find that in two days the zinc in the cells in which the carbon forms the copper pole gets quite black, whilst the others remain bright. Will W. J. Lancaster, or some other electrician, tell the cause and remedy?—ODD FELLOW.

[46617.] —**Sewer Gas.**— Can any reader of the ENGLISH MECHANIC suggest a simple mode of testing whether sewer-gas is forcing its way into a house through closets or bath-drains?—C. G. N.

[46618.] — **Connecting Bourdon Stop with Pedals** —Will "J. D.," "An Adept," or some other of our contributors, kindly favour me with the best plan for connecting a bourdon stop (placed at the back of a small organ) with the pedals? The pedals are now connected with the Stopped Diapason by the Great to Pedal coupler—that being the only bass on the organ at present. Also, as to what length I should cut the pine boards for the 8ft. and 4ft. pipes, and the length of blocks?—the diameters being respectively 8in. × 7in. and 4in. × 3½in.—G. E. S.

[46619.]—**Tricycle.**—Having fitted up a tricycle, geared level, which was rather hard work in mounting hills, I have now fitted a 2⅝in. wheel to crank, gearing with intermediate wheel 5⅝in. with 4¼in. wheel on hub, dia. of spoke-wheel 44in.—What size have I speeded the spoke-wheel down to? The spoke-wheel and hub-wheel are the same in both cases. Perhaps "Sunlight" or some of "ours" will kindly show the question in plain figures?—EX.

[46620.]—**Pantelephone Transmitter.**—To MR. JOHN C. FRANK.—I want to make the above form of transmitter, and shall feel greatly obliged if you will give me the following information—viz.: The size of diaphragm, and if you have tried a cork one; the resistance of the coil you use, and the amount of battery-power required for transmitting? Have you tried carbon and platinum, and if so, did you find it better to use carbon only? What is the size of the carbons, and how large are they at the actual points of contact? What receiver do you use?—A. J. S.

[46621.]—**Dynamo Electric Machines.**—I have made a dynamo-electric machine similar to one described in another paper by Mr. Urquhart. I have made the iron ring of armature of one continuous length of No. 18 soft iron wire, and I have wound the coils of c. c. wire (8 in number, each about 30ft.) directly upon the iron wire ring, and soaked the whole in melted paraffin. In place of a permanent magnet I have used an electro-magnet which I had by me. The pole pieces are of annealed cast-iron. The ends of the coils are connected up exactly as described. I have revolved the armature at about 1,200 turns per minute, but cannot get the sign of a spark, or the deflection of a galvanometer, neither when the magnet is excited by a separate battery or connected to the collecting brushes. Should the coils of wire be insulated from the iron wire ring? Can any reader assist me? as I am—IN WANT OF HELP.

[46622.]—**Occultation.**—On Thursday, March 30th, whilst examining the moon with a power of 70, a star was noticed a short distance from the unilluminated limb, which, after a short interval, was seen to be steadily nearing the moon. A reference to the *Nautical Almanac* showed that no occultation took place about this time—the nearest being that of 14 Sextantis at 13h. 52m. 23s. So implicit was the trust placed in the "Nautical," that no further attention was paid to the star until it forced itself upon my notice by its evident moonward path. It was now closely watched, and at 9h. 12m. 48s. (local time) was instantaneously "snuffed out." No star is as near the moon's assigned place for March 30th, 9h., as π Leonis, and the occulted star certainly appeared of the fourth magnitude. π Leonis was searched for in the vicinity of the moon, but could not be found. Clouds prevented me observing the reappearance. Can "F.R.A.S.," or any other reader of the "E. M.," account for this singular occurrence? The instrument used was a 3 7-10in. achromatic, and the watch might have an acceleration error of about 3m.—W. S., Sheffield.

[46623.] — **Numbers of Midland Coaches.** — Could any of your readers inform me of the plan on which the Midland Railway number their coaches? I have lately seen three bearing the same number.—DUNBRITTON.

[46624.]—**Heating Room for Drying Powders.** —Will some reader kindly inform me how I can best dry powders in a room, and how best to heat the room economically?—DELTA.

[46625.]—**Wife's Liability.**—To MR. WETHERFIELD. —A wife separates from her husband without an order of protection, and commences business on her own account. Gets into debt, and refuses to pay, though she has a stock of goods on her premises. What chance is there for a creditor? Whom must he sue?—the husband (still living in the neighbourhood), or the wife.—KARL.

[46626.]—**Chemical Balance.**—Instructions (with full working drawings) to make a 15in. balance that will weigh 500 grains in each pan, and turn with 1-1000th of a grain, will much oblige. I have made a 12in. that indicates 1-100th of a grain, but cannot succeed in making it more delicate in indicating weight in pans when loaded with 500 grains in each. Hope some of the many competent and old contributors will come to the rescue.—HYDROCARBON.

[46627.]—**Measuring Polarisation in Batteries.**—Could any of your readers kindly inform me, through your valuable correspondence column, how to measure polarisation in different batteries? I can find nothing respecting this measurement in any of my text books. Also, what is meant by the "absolute" system of units in electricity?—ELECTRIC.

[46628.]—**Watch Escapement.**—I wish to be informed of the means watchmakers employ to examine the contact of the lever with the ruby pin in English lever, the plates being pinned together. Also, if levers are made having stone faces in the notch as the pallets have? And whether the fact of a watch, after it has been stopped by the finger, not going on again without swinging the balance, is a sign of defective escapement? —PENDULUM.

[46629.]—**Chemical.**—1. A large quantity of ammonium chloride has turned bluish from being left in a brown paper parcel for some time. How can I purify it? I am going to label afresh all bottles in the laboratory (containing the ordinary chemicals). Where could I get printed labels? What good book is there on organic chemistry suitable for fairly-advanced students?—W. G. WOOLCOMBE.

[46630.]—**Steam Launch.**—Can Mr. Lancaster or some of "ours" kindly give me any information on the following?—I am building a boat 18ft. keel, 5ft. beam; what size boiler and engine will it require to drive it at a speed of, say, eight knots per hour? What size will cylinders and length of stroke be, and also the size of the propellers? and what pressure of steam will it require? Any other information will oblige—NEW ZEALAND.

[46631.]—**Somerset House Analysts.**—How do these gentlemen obtain their situations?—Is it by examination? I should be glad of any information as to the mode of appointment as well as the salaries offered.—SOUTH KENSINGTON.

[46632.]—**London Examinations.**—Can any reader tell me what "mixtures" have been given for analysis of late years at the first B. Sc. Honours Examination?—ZERO.

[46633.]—**Organ in St James's Hall, London.** —As the scheme of this organ is a rather unusual one, will "L. R. D." kindly give particulars as regards the solo stops and the effect of the full organ? Also, pressure of wind and name of builder, if possible?—C. H. D.

[46634.]—**Fixing Electric Wires.**—(1) What is the proper way, and with what tool should domestic telegraph and bell-wires be strained, and how then be fastened and kept taut? (2) How should joints be made in same? Should joints be soldered, or how made secure in out-of-the-way places—as in the roof of a house when a soldering-iron would get too cold before one could reach the joint? (3) Through how many yards of wire should two Leclanché cells work a bell?—MEME.

[46635.]—**Imitation Marble.**—Can this be made with Portland cement mixed with other ingredients? Is borax used? Particulars of mixtures and mode of manufacture will oblige. Are any books published giving information on this subject? If so, please name them.—HYPO.

[46636.]—**American Cloth Sticking.**—I have a knee-hole table covered with American cloth which has become rather troublesome in consequence of my papers occasionally sticking to the cloth. Can anyone say how that may be cured?—B.

[46637.]—**Mount Cutting.**—Can anyone tell me if there is any simple way of cutting out square card mounts for photographs? I can cut them out with a sharp knife by laying the card on glass, but I cannot get the bevelled edge.—No Sig.

[46638.]—**Fresh Water Fish.**—I have a large pool of water used as storage for driving a water-wheel. It is supplied from a limestone district, which makes the water hard. Would it be possible to keep any kind of fish in this pool, and which would be most desirable to have?—Culvert.

[46639.]—**Waterwheel.**—Please inform me how to calculate the horse-power of a water-wheel 12ft. diameter 2ft. 9in. wide. Feed-pipe being 4in. hole, cast-iron, lead jointed for pressure from a reservoir 10 yards square, 2 yards deep, 100ft. from wheel at a rise of five yards above the discharge of pipe on wheel.—E. Morgan.

[46640.]—**Electric Dancing or Working Figure.**—Will any reader kindly give me a few instructions how to set about making one of the above? I want one that would stand on a small side-table, so that I could start it without being observed. I want one that will work for about 20 minutes. I have set up three cells of Mr. Bennett's battery, and I find they ring a 2½in. bell exceedingly well. Could I work the above with the same battery, as I do not want anything very expensive?—J. H. M.

[46641.]—**Electric Bells to Connect.**—I want to ring two bells with one battery—not both together, but one at a time. The battery is placed at house, and a bell at stables about 400 yards away. This bell is in working order. I want now to ring another bell at lodge gate about 200 yards from stables. Must I put down two more wires besides those running to stables to ring bell at lodge? Or, can I use the stable wires as far as they go—one or both? If so, how? Or, must I run one additional wire, &c.? A sketch showing connections and simplest and cheapest method would greatly oblige—F. H. M.

[46642.]—**Drilling Fluid.**—What are the best ingredients to use, and in what proportions, for a fluid to use in turning and drilling steel and iron? We use soap and water and olive oil in varying quantities, and as we use a lot, we want to know if there is anything better and cheaper in the long-run.—Kismet.

[46643.]—**Division Plate.**—Will one of our lathe correspondents kindly give the following information?—I want to get a division plate with holes from 360 down. What is the least number of rows, and their number of holes, with which I can divide from 2 to 360? As I shall want this plate to use in cutting change wheels, &c., and very often I require a wheel with an odd number of teeth, and not knowing what that number might be until wanted, it is for that reason I wish to have a plate that will divide anything between 2 and 360, with as few rows of holes as possible. I have been at it myself, calculating for several hours, but as I am constantly interrupted, I find it a very long job. Please do not advise a micrometer with change wheels, as I must have a division-plate.—Kismet.

[46644.]—**Painting.**—Through the instructions of Mr. King I have contrived to make a light cart, and am glad to say better than I anticipated. I am now at a loss as to painting. Will Mr. King, or some kind reader, instruct me? I have seen what is called dead painting (no gloss). I understand it takes the varnish better, and wears longer. How is it done? Will someone give me instructions, or cannot someone give us something like practical notes on painting?—the same as Mr. Davies has done on plumbing. It would be a great boon, not only to me, but to a great many contributors.—Cambridgeshire Boy.

[46645.]—**Astronomical.**—I should be glad if any of your astronomical correspondents would be so kind as to inform me of any book containing tables giving the value of 1″ (of arc) for every degree, or less, from the North Pole to the Equator. I know, for instance, that 1 sec. of time = 15″ of arc at the Equator. But what is its value at, say, N. Dec. 45°? Or if no book gives this, would "A Fellow of the R.A.S.," or some other correspondent give the value for every 5° or less (if not too much trouble)? as I fear I am not mathematician enough to calculate it for myself, from given formulæ.—J. Atkinson.

[46646.]—**Marking Ink.**—I had the following given me as a recipe for a marking ink, which requires no heating:—Dissolve one drachm of lunar caustic in ½oz. distilled or rain-water, add liquid ammonia until the precipitate formed is redissolved, and gum-water to make up the quantity to 1oz. I made some three weeks ago, but it is a long way from black yet. How long should the above take to go black? I put a small quantity in the sunlight. I have not tried it to mark with, but it has turned a greenish colour, and seems full of sediment. The other, which is indoors, but not exposed to the direct rays of the sun, is a dark browny red, and quite clear from sediment. Are the above proportions good, and can someone give me a better recipe (to require no heating)? What is the difference between lunar caustic and nitrate of silver—and will not either do just as well?—Kismet.

[46647.]—**Astronomical.**—Looking at the star Omicron Leonis the other night with a 3in. telescope, I saw a faint companion within 10″ following the bright star. I do not find this in Mr. Webb's book, nor is it marked as double in Mr. Proctor's small atlas. Is it new? I was looking for the red var. star R, which I could not find. What is its present mag.?—J. A.

[46648.]—**Chimney on Girder.**—A chimney-stack is to be carried by a girder. How is this done as regards the projection of jambs for fire-place? Would it be safe simply to corbel out the brickwork to the required projection?—Querist.

[46649.]—**Mounting Micro. Lenses.**—Will anyone tell me how many threads to the inch is the standard for screws used by opticians in microscope work? And, will anyone further tell me how to mount lenses in their brass seats? Is putty-powder (as sold by the chemists) suitable for polishing lens? Or, is there a kind specially prepared for this work?—Micro.

[46650.]—**Electrical.**—1. How can I determine strength of current in a battery? 2. If two currents are measured by two different tangent galvanometers in two different places, show what you would require to know, besides the deflection observed, in order to compare the strengths of the two currents?—H. W. Wager.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, April 12, and unacknowledged elsewhere:—

W. Billson.—Phosphor Bronze Co.—Rev. H. Ash.—W. A. McClintock.—Leroy and Co.—W. Granger.—Capt. King.—J. McAdorey.—S. Wood.—J. N. Dufty.—J. Dresser.—J. C. King.—Tempus.—W. Unsworth.—Idris.—J. H. H.—T. Mackenzie.—Surgeon.—W. A. S.—A Brother Exhibitor.—Grateful.—T. A. C.—G. Gilbert.—C. Newton.—China Rivet.—Propeller.—Dixhuit.—Engineer.—Capt. Curtis.—W. N. B.—P. Mooney.—W. J. R., Chelsea.—J. W. H.—Jack of All Trades.—S. Mills.—T. Mudd.—J. H. Anderson.—Fellow-Workman.—LL.B A.—A. B. M.—Jas. Lewis.—Sunlight.—Dr. Edmunds.

J. T. Stevenson. (If you will kindly say what sort of an alarm you require, we may be able to assist you. We have given all sorts, from a simple mechanical device to knock down a tea-tray, &c., to an elaborate electric arrangement to ring a bell until it is stopped.)—Mrs. Grocegreener. ("Properly diluted" is sufficient. The solution is not injurious, and all you have to guard against is using it too strong. In the red form it is used as it is for bathing wounds and ulcers, and you have merely to try it on your own tongue and get at the right degree for the dog. It is simply unpleasant, if too strong—that is all.)—An Amateur. (If you object to the shot, use a strong solution of common soda. Good corks and just a little carbonate of soda suffice for the rest. 2. Only by means of caustic to burn it out, which would probably be deemed worse than the "disease.")—A Sufferer. (Try acetic acid, protecting the surrounding skin with a shield; or use the soft plasters with holes in them, and the corns, relieved from pressure, will become callous and easily removable.)—Electro. (See pp. 110, 203, 489, last volume, especially p. 489, No. 879, and get the catalogue there mentioned. See also p. 33, No. 808.)—Weakness (Spectacles evidently not suitable; but it is purely a question to be answered only by examining the patient.)—W. B. Halbech. (Your criticisms of existing brakes have been made many times, and the description of your invention was given as fully on p. 18. Has it ever been tried?)—Aeronaut. (A balloon 48ft. high by 36ft. in diameter will carry three persons, and when full it holds over 18,000 cubic feet of gas. You can either increase the height or the diameter to obtain a capacity of 20,000ft.)—An Old Subscriber. (A plate containing 50 sq. ft. is rather a difficult job for a novice; but if you look again through the indices you will find references, and in the last number, p. 116, answer to "Mirror," a brief description of the mercury process.)—Erin-go-Bragh. (You can dip the rubber into bath of melted sulphur, or masticate it by a machine, and sprinkle washed flowers of sulphur in; but if you wish to experiment you should read the Cantor lectures on the Indiarubber Industries in Vols. XXXI. and XXXII., especially the portion on p. 562, No. 804. The lectures are published in book form for 1s. by the Society of Arts, John-street, Adelphi.)—Oh. (1. We do not know. 2. See an article on the "Micrometer" in No. 471. You will find several varieties described. See p. 253, last volume, and the indices generally for information; but as to making one, are you possessed of the requisite skill and the machine tools necessary?)—Dutch Subscriber. (The diameter of No. 14 Birmingham wire gauge is approximately 2·15 millimetres. See answer to H. J. Peerlhaup, p. 115, last week.)—Delta. (Practical directions for making bichromate batteries were given in Nos. 726 and 728, p. 585 and p. 630. See also p. 65, No. 731, and p. 137, No. 734.)—Hawksbee. (Do you not think that an elementary textbook would be the best authority? You will not find a direct answer; but by a little study you will see that such a question cannot be answered without other data. The ampère is the unit of current, and is the current through a circuit of E.M.F. 1 volt, and resistance 1 ohm. 2. It depends entirely upon the university. In some the writing of a thesis (which can be done sub rosâ by somebody else), and the payment of £20 is sufficient. If you mean to study, you have choice of Berlin, Heidelberg, Freiburg, Gottingen, &c., and the cost of living is less than here. The fees will vary, but at Berlin would be less than in London.)—Amateur. (See the indices of recent volumes under head of "Electric Motors," and adopt one of them, as we presume you mean the modern style.)—Country Bodi. (See previous reply. 2. Probably a coil of platinum wire made incandescent.)—David Williams. (We may do so by-and-by, or write a fresh article. 2. The grease can be removed by rubbing with weak solution of ammonia or by means of benzoline and blotting-paper, but as to re-dyeing that is not easy. See a recipe on p. 273, No. 792. You will want suitable plant.)—Jack. (For such things use the aniline dyes. There is nothing so easy, and nothing better.)—Ton. (Have you tried the German? You require a pyrometer, such as Bailey and Co., of Salford, make.)—J. Forbes Mitchell. (We do not understand what is meant by the term "transfer." If carbonic, for producing several copies of writing, any large stationer supplies it.)—Querist. (Portland cement, 1; sharp sand, 5. Yes. In back numbers you will find plenty about heating apparatus.)—Puzzled. (The instructions are clear and precise, and others have found no difficulty. We can suspect only that you have used common soda instead of caustic soda, or that you have placed the borings in the porous cell and the solution in the tin can.)—Jas. Lewis, Swansea. (Do you mean real Japan, or ebonising? If the former, varnish with proper Japan, and bake in a suitable oven.)—J. H. K. (We fail to understand the first question. If the dial is horizontal, it must make with the style an angle equal to the latitude of the place, the style preserving its parallelism to the earth's axis. If a vertical dial, the angle formed by the dial plane and the gnomon must be the complement of the latitude. See p. 592, No. 805, and the indices generally for much information on the subject. If Newport, I.W., will do, that is 15min. 5sec. slow compared with Greenwich mean time.)—G. Murphey. (It is sent post free for 12s. 6d. by the publisher, J. Tripolin, 5, Bartlett's-buildings, E.C.)—Amateur Electrician. (Sprague's "Electricity," Spons, and Prof. S. P. Thompson's "Electricity and Magnetism," Macmillan.)—H. S. (We believe we answered at the time. The Pharmaceutical Society publishes a pamphlet giving all the particulars. It can be had at the society's rooms, 17, Bloomsbury-square, W.C. It is not necessary to learn Latin—merely a few words of the language, and the technical meaning of a few phrases.)—E. S. B. (Given in all sorts of forms in back volumes. See p. 400, No. 797.)—A Four Years' Sufferer. (Your questions were really answered by silence. If any special attentions were necessary, they would have been mentioned.)—Edinburgh. (We are not aware that any one has succeeded in working a launch with such an engine, but see reply 46520 in this number.)—R. Barraclough. (The subject has been frequently referred to in our columns. You can easily make a gas-stove with a Bunsen burner, and if you like, heat water with it. See the indices.)

THE LATE "SECONDS' PRACTICAL WATCHMAKER"

Additional subscriptions have been received, as follows:—

	£	s.	d.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions, and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

Holloway's Ointment and Pills.—All ulcerations, sores, abscesses, bad legs, and skin diseases are best treated by these medicaments. The Ointment eradicates all noxious taints, and makes every symptom assume a milder form; and this desirable result is made doubly certain by the purifying, regulating, and alterative power of the Pills.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

Epps's Cocoa.—Grateful and Comforting.—"By a thorough knowledge of the natural laws which govern the operations of digestion and nutrition, and by a careful application of the fine properties of well-selected Cocoa, Mr. Epps has provided our breakfast tables with a delicately-flavoured beverage which may save us many heavy doctors' bills. It is by the judicious use of such articles of diet that a constitution may be gradually built up until strong enough to resist every tendency to disease. Hundreds of subtle maladies are floating around us ready to attack wherever there is a weak point. We may escape many a fatal shaft by keeping ourselves well fortified with pure blood and a properly nourished frame."—*Civil Service Gazette.*—Made simply with boiling water or milk. Only in Packets labelled—"James Epps and Co., Homœopathic Chemists, London." —Makers of Epps's Chocolate Essence for afternoon use.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 8d. for the first 24 words, and 8d. for every succeeding 8 words.

◆◆◆

Organ Bellows and Windchests, several in good condition (ready for wind and pipes); books, musical instruments, or offers to W. Johnson, 12, Moxley, Wednesbury.

Large Plate **Electrical Machine** (3ft. diameter), conductor and stool, in exchange for other physical or chemical apps., or tricycle.—Lecturer on Physics, Central Science Schools, High-street, Marylebone-road.

Fretwork Machine new, prize Holly; exchange for violin and bow.—W. T. Kent, 68, Westbury-street, Swansea

Wanted to exchange 50in. Special Challenge **Bicycle**, nearly new (can be seen), for small sailing-boat.—A. W., 62, Cranham-road, South Bermondsey.

For **Engraving** Music Plates, one alphabet capitals, one alphabet small letters, punctuation; all the musical characters, new. Exchange for 48in. Bicycle, or other useful article.—Green, 13, Sepulchre-street, Sudbury, Suffolk.

Bicycle wanted, in good condition, in exchange for good ½-plate camera, lens, and apparatus. Send for particulars. —W. F. James, Fairfield, Chudleigh, Devon.

Launch Engine, new, 5 by 5in. stroke, exchange for 52in. Bicycle. Must be a good article.—Andrew Dryden, Amble, Acklington.

Forty-five 1s. 6d. monthly parts of "**Imperial Cyclopædia** of Machinery," by MacKenzie. For offers; a good lever watch wanted.—69, Newton-street, Millom, Cumberland.

"**Le Merveilleux**," by Lancaster, with lamp, bath, and dozen dry plates; new. Exchange architectural books, or water-colours.—Frank Toyne, Clarkgrove-road, Sheffield.

Tricycle, bell crank, 50in. driving-wheels, chainless, exchange for good secular or operatic musical box.—G. W. Wright, Sedgley-road, Woodsetton, near Dudley.

Brass-fitted **Shower Bath**, good order, for second-hand bicycle, guitar, or offers.—E. Wright, 7, Clements-road, Bermondsey, S.E.

Organ-pipes, wood and metal, taken from a church barrel organ. Also a keyboard. What offers?—W. Saunders, Dickleburgh, Norfolk.

Dulwich. Splendid 8-room **Villa**, mortgaged to Starr Bowkett Building Society for £300, free of interest, for 12½ years. Offers in exchange.—37, North Cross-road, E. Dulwich.

A Howe Treadle **Sewing Machine**, in good working order. Also two patent gas-fires, complete, new. Exchange tools, or offers —W. R. Slater, Sunderland.

Superior 4-keyed concert **Flute**, in handsome case; Cassell's "Natural History"; other articles. For lever watch, Wray o.g., or other offers.—T. M., Stretton-Stop, Rugby.

Wanted, 10 by 8 Rapid Rectilinear or **Symmetrical** lens, and 10 by 8 wide angle landscape lens, in exchange for Ross's No. 3 portrait-lens, cost £17.—L. 24, Barrington-street, Limerick.

Demas **Lathe and Fretsaw**, 1880 improved pattern, cost £3. What offers in exchange? Anything useful accepted.—A. Ino, 296, Hackney-road, London, E.

THE SIXPENNY SALE COLUMN.

For Sale.

"**The Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—F. Robertson, 13, Greek-street, Soho, W.

Metallic "E" **Violin Strings**. Infinitely superior to Gut. Three, post, 1s.—Smith, 2, Bedford-street, Plymouth,

The **Britannia Company's** new No. 13 Screw-cutting Lathe, 30in., strong and accurate, price £15 15s. See notices in English Mechanic. Apply for circular, 1 stamp.—Britannia Company, Engineers, Lathe Makers to the British Government, Colchester, England.

Launch Engines, new, different sizes, cheap.—State size required.—John Middleton, 16, Hope-street, Glasgow.

Parkinson's Amateur **Polisher's Cabinet**. The most inexperienced can polish with success. Circular free.—James Parkinson, Warrington.

Japanning done for the trade. Machines of every description.—Merson and Co., 44, Wynyatt-street, E.C.

Bicyclists, Athletes, and Engineers should wear the patent nickel-plated steel Albert, new and elegant pattern; always retains rich polish. Does not rust. Post free 12 stamps. —Gorse, 128, Moor-street, Birmingham.

"**Fiddler's**" double soundboard **Violin**, loud and clear, 10s.—"Fiddler," 19, Edward-street, Burdett-road, E.

Paints.—Instructions for Making Paints suited for the grinder and operative painter.—T. Armstrong, Woodville, Hounslow.

Bachelor's **Brass Buttons**. No coming off. No sewing. Last lifetime. Packet free, 14 stamps.—Hezmalhalch.

Excruciatingly **Comic Readings**. You will be obliged to laugh. Send 1½d. for one, and rejoice.—Hezmalhalch.

New "Eclipse" **Pipe**. No oil in mouth. No smoking wet tobacco, 2s. free.—J. Hezmalhalch, 1 Fellisclifffe, Leeds.

The **Dental Wonder**, a marvellous cure for toothache, post free, 1s. 2d.—Southwell, Pharmaceutical Chemist, Boston, Lincolnshire.

Southwell's Absolute **Remedy** for Tic Douloureux, post free 2s. 9d.—Southwell, Pharmaceutical Chemist (by examination), Boston, Lincolnshire.

Microscopic Objects for mounting. Sample 20 preparations and price list, 1s, 2d.—R. Philip, Grove-street, Stepney, Hull.

Sufferers from Indigestion, &c., should read Dr. Brearey's "Popular Treatise" on that subject.—Address the Author, enclosing 7 stamps, 1, Belle Vue-square, Scarboro', for copy.

Fisher's Ethoxo-hydrogen **Limelight Apparatus** gives the most brilliant and whitest light. Perfectly safe.

Ethoxo-hydrogen **Generator**, made in copper, price 30s. Send stamp for particulars.—Fisher, Calverley-street, Tunbridge Wells.

Ingredients for preparing Hop Bitters, 6d. per packet, post-free, 8d.—Jones, Chemist, Westminster-road, Liverpool.

Rubber Stamps. How to make them; detailed illustrated instructions post free 13 stamps.—Watson and Co., Canning-road, Wealdstone, Harrow.

Good **Black Silk**, 3s. per yard, stamp for pattern.—M., 5, Lenham-road, Lee, S.E.

A **Rare Opportunity** Offers for a steady Mechanic who understands sewing machines, to take a share in old-established business in a large provincial town. Capital required, £200.—Address, W. T., English Mechanic Office.

Universal Trade and Amateur Supply of Scientific Apparatus, wholesale, retail, new, second-hand, cheap, reliable. —Caplatzi, Science Depot Hire and Exchange.—Chenies-street, W.C.

Electric Stores.—Unapproached for quantity, variety, and cheapness especially. Frictional Machines, Coils, Batteries, Motors, Telegraphs, Bells, Wires, Fittings.—Caplatzi.

Electro-Motors for Rails, Boats, Pumps, Vacuum Tubes, &c., 20s. to 30s. 9in. Armature, Wheels, Axis, Commutator, 10s. Magnets, 3s., 5s. Full instructions.—Caplatzi.

Intensity Coils, Magnets, Bells, Telegraphs, best Medical Coils, Batteries, Vacuum Tubes, &c.—Caplatzi.

Lathes.—Engineer's, Watchmaker's, Dentist's, Seal Engraver's, Lapidary's, Lens Grinder's, Parts, Tools, and Belongings, 30s, 60s., £3, £5, £8, £10.—Caplatzi.

Presses, Lithographic, Copperplate, Printing, Stamping, and Rolling, Flatting Mills, Anvils, Vices, Grindstones, Emery Wheels, &c.—Caplatzi.

Entertainments.—Grand Display of Apparatus on hire weekly, at 2s. per £ value. Electric Light Sets, £3. Dynamo-Machines and Motors.—Caplatzi.

Measuring Instruments.—Resistance Coils, Rheostats, Electrometer, Magneto-meter, Electric Counters, Tangent, and other Galvanometers, Torsion Balances, German Silver Wires.—Caplatzi.

Interference Line Micrometer Dividing Engines, Micrometers, Sectors, Gauges, Clockworks, Cog and Bevel wheels of all sorts.—Caplatzi.

Telescopes, 2, 3, 4in. Refractors, 3, 5, 6in. Reflectors. First-class Stands, O G.'s, Eyepieces, Tubing, Finders, and accessories. Complete mounts.—Caplatzi.

Spectroscopes, Table, Direct Vision, Pockets, best makers, Prisms, Nichol's, Camera Lucidas, Iceland Spars, Dense Crown, Flint for best Prisms and O.G.'s.—Caplatzi.

Electric Light. All Requisites, large and small, as lamps, batteries, carbons, chemicals, wires, screws, dynamos, magnetos, materials, &c.—Caplatzi.

Frictional Machines, 8, 12, 15in. cylinders, 10s., 15s., 20s., 30s., 40s., all accessories. Polytechnic Leyden jars, 4 gallons, 10s. (not glass price). Plate machines, half-price.—Caplatzi.

Microscopes, accessories, large number. Powel and Lealand, £12; Browning's Binocular, £7; Society of Arts', 40s., 50s.; Youths, 5, 10, 20, 30s.—Caplatzi.

Castings, Photographic Flange, Telescope Cells 9d. per lb., Racks, Tubing, Screws, Tripods, &c., Iron Stands for Micro. and Telescopes.—Caplatzi.

Warrants all supplies; no toys or catchpennies, 20 years established. Inspection invited. Beware of imitators. No cheaper house.—Caplatzi.

Photo Apparatus. Our Stores are replete with cameras, lenses, and all accessories, speciality stands, bellows for fitting to camera, best single and double backs, &c.—Caplatzi.

Model Department. Very cheap Engines, Boilers, Boats, Cylinders, Fittings, Materials, Wheels, parts of all kinds up to 1 H.P.—Caplatzi.

Chemistry. Large Stores of good second-hand apparatus at half price. Noted for balances, graduated glass, cabinets, bottles.—Caplatzi.

Particulars Weekly. Catalogue 2d.—Dr. Caplatzi, Science Depot, Hire and Exchange, Chenies-street, Tottenham Court-road. Near University College and British Museum, and five stations.

Perambulator, superior bicycle wheels, Hood, porcelain handle, 36s.—G., 428, Edgware-road, W.

Bicycle, Paragon, bright, in good repair, £3 10s.—J. Dibb, 72, Old Oak common, Willesden Junction.

Magnificent and Novel **Slides** for the Polariscope; sample 8 stamps.—William Crewe, 16, Machell-road, Nunhead.

Japanning. Machines, Scale Beams, **Trunks**, Baths, &c.—J. Campbell, 9, Clare-street, Halifax, Yorks.

Oxygen Generator (never used), no gas-bags required, for anything useful.—Francis, Rochford, Essex.

Dynamo Machine for hand power, complete set parts, iron and brass castings, wire, &c., 30s.—Patrick.

Incandescent (carbon) **Electric Lamp** and five-cell Battery, 26s.—Patrick, 15a, White Lion-street, Chelsea, S.W.

Fretwork Sheets for Sale, cheap, 20 blocks 22 by 17.—Particulars, T. Stopher, Wood Carver, Ipswich.

Rings, pure Nebaska Gold, Ladies', set with pure paste gems, 2s. 6d free.—Editor "Dulwich Register," Blenheim-grove, Peckham.

Lockets, pure Nebaska Gold, highly finished and newest patterns, 3s. 6d. Large size, 5s. 6d. Diamonds and rubies, 8s. 6d., free.—Above.

Bracelets, not to be told from pure gold, very handsome, 4s. and 6s. 6d. Rubies, diamonds, and pearls, 10s. 6d., free. —Above.

Rings, wear like fine gold, Gent's, set with diamonds, 3s. 6d. and 5s. 6d., post free. Send size.—See below.

Watches, highly finished, in pure Nebaska Gold cases, Gent's 18s. 6d., Ladies 21s., keyless 30s. and 35s.—See below.

Any **Article** sent on approval on receipt of a Postal Order or stamps—Editor "Dulwich Register," Blenheim-grove, Peckham.

Metallic "E" **Violin Strings**. Gut quite superseded and out of date. Four post free, 1s.—John Elarco, 36, Kelvin-grove, Liverpool.

Great Success. Ladies' Beautiful **Cloth Dress** for 8s., best quality; patterns 2 stamps.—Firth, Kirkgate, Wakefield.

Splendid 44in. Open-fronted **Tricycle**, direct spokes, patent hill gear, will climb any hill, new last October, price £10, cash.—Firth, Kirkgate, Wakefield.

New **Violin** by "Fiddler," with good, full-mounted octagon bow, complete 21s.—W. Witton, Pennfields, Wolverhampton.

Hardy Irish **Ferns**, 10 varieties, good strong plants, 1s. 2d. doz., free.—M. Colin, Innishannon, Co. Cork.

Beautiful **Monograms**, 40 sheets notepaper with initials in gold, 7d.—Penby, 70, Bevenden-street, Hoxton, London.

Alpine Auricula Flowering **Plants** of the finest strain, 2s. 6d. doz., free.—James Dixon, 26, Fellside, Kendal.

Hardy **Lake Ferns**, Asplenium Viride, Lastrea Rigida, Colina, Montana, Dilitata, Parsley, Polypodium, Robertianum, Cystopteris, Dentata, Trichomanes, free, 14 stamps.—John Burns, Cliff Brow, Kendal.

Lathe for sale, 4½in. centres, 3 speeds, and slide-rest, £4.—G. P., 14, Nunthorpe-road, York.

Launch Engine, 3½ by 4½, link-reversing motion and pump, £5 10s.—Parker, Octagon, Plymouth.

Lantern Photographs, 10,000, with readings, from 6d plain, 1s. coloured.—A. Pumphrey, Emily-street, Birmingham.

Gelatine Films for photographs, reduce cost and labour of photography to minimum.—A. Pumphrey, Birmingham.

The **Filmograph** carries 100 films or 12 plates. Lightest Photo. Apparatus. Illustrated tests.—Pumphrey, Birmingham.

Filmographic Manual, free 6d., with photograph from Film Negative. Full instructions. Films, Filmograph.—A. Pumphrey, Birmingham.

100-Fold **Filmograph Slide**, can be used with ordinary camera. Plates changed anywhere.—A. Pumphrey, Birmingham.

Dry Plates, perfectly instantaneous. Every reader can have samples for 6d.—P. Mitchell, Sydenham, S.E.

Three-Horse **Engine** and Boiler, complete, £15 (given up business).—R., 36, High-street, Welshpool.

Kneading Machine, nearly new, cost £6, sell for £2 (given up business), suitable for family or small bakery.—R., 36, High-street, Welshpool.

Spring Balances (warranted correct), to weigh from 1lb. to 400lb., price 5s. 6d.—James Parkinson, Golborne-street, Warrington.

Sample **Bottle of Polish**, as above, with instructions, post free, 1s. 4d.—James Parkinson, Golborne-street, Warrington.

Slide-rest, 10in., £3, combined engine and boiler, 4¾in. diam. cylinder, £17.—234, Swan-road, West Bromwich.

Collographic **Photographs** for Machinery and Trade Patterns. Sample and list for 2d.—Pumphrey and Day, Birmingham.

Rubber Stamps.—Full instructions for making them without previous experience, 4d.—98, Devonshire street, Sheffield.

Rubber Stamps, 1s. each, monogram 1s. 1d.; Name, 1s. 6d. Warranted complete. Particulars one stamp.—Devonshire-street, Sheffield.

Strong-seamed **Copper Boiler**, 3½in. by 7½in., with water gauge, steam dome, union, whistle, manhole, safety-valve, and tap, 10s.—Adpha, Wellington, Somerset.

Prismatic Circle, beautifully made, with tripod, cost over £20, Five Guineas.—Grocer, 54, High-street, Stoke Newington, London, N.

Dipleidoscope, by Dent, with book of instructions, price, 25s.—Grocer, 54, High street, Stoke Newington, London, N.

Telephone Transmitters and Receivers, by Newton and Co., are the simplest, cheapest, and best.—6, Hill-street.

Firms and Institutions whose premises are too extensive for speaking tubes to carry, should have Newton and Co.'s Loud Speaking Telephones, 6, Hill-street, Birmingham.

Gower Bell instruments are furnished with two ear tubes, so are those by Newton and Co., and quite as loud, and clear of all patents.

Incandescent Lamps, 2s. 6d. each.—A. Grove, Lower Sydenham, S.E.

First-class new **Clarabella Stops**, voiced, 14s. each.—Green's Pipe Factory, Ipswich.

Printing Office, Two Presses, 11 Founts Type, &c., cost £21, sell £10 10s.—P. Whitton, Henfield.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, APRIL 21, 1882.

TRIPLE EXPANSIVE ENGINES.

THE success of the compound principle in marine engines has been so great in recent years, that it is not surprising some adventurous spirits have sought to obtain greater economy still by means of three cylinders, expanding the steam from high pressure through three stages, and the discussion at the recent meeting of the Institution of Naval Architects may possibly help to throw some light on the subject, though it is evident that great diversity of opinion exists. The subject came up for discussion on a paper read by Mr. Kirk, of the firm of R. Napier and Sons, in which that gentleman described the triple expansive engines of the screw-steamer *Aberdeen*, one of a class which makes the long voyages between Australia or China and this country, in which even a small saving in coal becomes of considerable importance. In 1874, a vessel was fitted with engines of the triple expansive type, working with steam having a boiler pressure of 150lb. on the square inch; but unfortunately the boilers failed very early, and had to be taken out, so that the experiment came to nothing, and it was left to Messrs. Geo. Thompson and Co. to give an order which enabled another step in advance to be made. The engines of the *Aberdeen* are practically of the same design as those of the earlier vessel, being respectively 30in., 45in., and 70in. in diameter, with a stroke of 4ft. 6in. The boilers are two double-ended ordinary pattern, made in steel with six Fox's corrugated furnace-tubes, giving a total heating surface of over 7,000 square feet. The pressure is 125lb., there is no superheater, and while the high-pressure cylinder is not jacketed, the intermediate is surrounded by steam of 50lb., and the low-pressure cylinder with steam of 15lb. above the atmosphere. On her trial the vessel consumed 1·28lb. of coal per indicated horse-power, a rate which may be taken as equivalent to 1½lb. in ordinary work. The percentage of steam condensed in the jackets, carefully measured into a tank, was nearly four per cent. of that admitted to the high-pressure cylinder, and a subsequent experiment showed that the loss of steam between the high pressure and the low pressure, added to the steam condensed in the jackets, was about the same as took place when the steam was shut off from the jackets. That is simply what might be expected, but it does not show a real loss, for, as has been frequently pointed out, it is cheaper to use steam in heating jackets, than to lose it by condensation in the cylinders. In the case in question the high-pressure cylinder was not jacketed, and there was consequently a considerable loss of heat in expanding into the intermediate cylinder, the very point at which it is most important, not to lose any heat that can possibly be saved. It may be asked why, if three cylinders are an improvement upon two, why should not four be an improvement upon three; and the answer must be that, putting aside the cost of the machines themselves, such an arrangement would give an advantage. Triple expansive engines have been made with the high-pressure cylinder placed above what in the ordinary compound-engine would be the high-pressure cylinder, thus driving on two cranks; but this arrangement is obviously open to the objection that if the ratios of expansion are approximately equal in the different cylinders, the strains are unequal, and so are the several ranges of temperature. Hence Mr. Kirk concludes that it would be better to have two low-pressure cylinders, and to put the high-pressure on the top of one, and the intermediate on the top of the other. It may well be doubted whether the gain in passing steam through four cylinders thus arranged would pay for the extra cost, especially as there would be the friction of two extra slide-valves and their gear to deduct. Theoretically, there is a gain, but practically, there may be losses which experiment only can determine, and therefore the performances of the *Aberdeen* will be studied with much interest by marine engineers. Mr. Parker, who had an opportunity of witnessing a trial of the new triple expansive engines, read a paper on the economy of compound engines, in which, after pointing out that there is a loss in the ordinary two-cylinder compound between the expansion of the steam in the high-pressure and its admission to the low-pressure cylinder, during which expansion no work is done, he emphasised the fact that in spite of that loss, which is really considerable in the best designed compound, the latter engine is more economical than the single cylinder, for the simple reason that the range of temperature is divided into two, and the condensation in either cylinder is not so great as in a single cylinder engine. But a limit is reached in which expansion in the two-cylinder engine produces a greater loss than gain; hence the endeavour to obtain, with higher pressure and a longer range of expansion, a greater degree of economy by means of three cylinders—a vessel having been recently completed in which the pressure is as high as 150lb. The discussion on the two papers was opened by Mr. Denny, who gave a practical turn to it by stating that he had a steam tender fitted with a boiler capable of carrying 120lb. of steam, with which he would make some experiments. At present she is fitted with an ordinary compound engine, and Mr. Denny will work her for some time at 90lb. pressure, and take account of the fuel used; then he will fit a third cylinder on the top of the high pressure, and work with three cylinders and 120lb. pressure, and compare the consumption of fuel. The results will be laid before the Institution probably next year, so as to give an extended trial, and we venture to think that they will be of more real utility than half the arguments used by those who perennially debate this question. Mr. Longridge contended that for every engine there is a pressure and a grade of expansion which give better results than any other, and argued that the economy of the compound is not due to the principle, but to the circumstance that the engine is worked expansively. He expressed great faith in superheating, and asked whether it was beyond the skill of engineers to produce a good superheater. Other speakers dwelt on the advantages of high-pressures, and Mr. Cowper called attention to the action of his "hot-pot," and dwelt on the importance of bringing steam into contact with hot surfaces. Mr. McFarlane Gray, however, said that the theoretical gain by raising the pressure from 60lb. to 120lb. was 14 per cent., which, in practice, amounted to about 12½ per cent., and he asked whether it was worth while to use three cylinders to gain that percentage. That, we imagine, is a question to be settled by experiment, for, as Mr. Kirk mentioned subsequently, theory and practice do not always coincide. In the mercantile marine it has been conclusively proved that compounding is essential to economy, but Mr. Kirk does not see much advantage in steam jackets with high piston-speeds, though they are, he acknowledges, serviceable in the case of low speeds. They convert the low-pressure cylinder into a boiler, but he thinks that the steam thus made is better drained away. He fails also to see much good in the "hot-pot," because the steam is not heated up with waste heat, and so on—doctors differing, who shall decide except Experience? Mr. Parker replied to some remarks of Mr. Longridge's by the statement that 60lb. steam had been tried with single cylinders in the *Circassian* for two Atlantic voyages, and the result was a stupendous failure. Experiments with and without jackets had been made in the *Aberdeen*, and the result was that practically there was little to choose—that the jackets gave so slight an advantage that it is not worth while complicating a machine by their use; but he clinched the whole question by saying that the consumption per ton per mile was the only point to which owners would pay attention, and that that is so complicated with the efficiency of the screw and the ship that it is not easy to arrive at any just conclusion as to the relative merits of different patterns of engines. That is the dispute in a nutshell. No marine engineer would nowadays think of using single-cylinder engines if economy was his object, and as to the best type of compound, experience only can give a definite answer.

THE SELLON - VOLCKMAR SECONDARY BATTERY.

THANKS to the lively controversy which has taken place between those who represent the Faure battery and those who are the inventors or owners of the patents of the new "accumulator," the public are learning something more of the construction of the rival batteries than could be gathered from a perusal of the specifications filed by the patentees. As exhibited at the Crystal Palace, where it supplies current to the Lane-Fox lamps in the Alhambra Court, there can be no doubt that the Sellon-Volckmar accumulator is really a practical success—whether it is superior to the Faure must be left to experts to determine. At the Palace, a battery of 39 cells supplies current to 200 lamps, nominally of 20 candle-power, for a period which may be as long as seven hours if the battery is fully charged. The candle-power in this case is, we believe, really more than the nominal system of reckoning makes it, for the carbons, owing to the steady working of the secondary batteries, can take a stronger current than they can from the dynamos. The exact construction of the Sellon-Volckmar cell cannot be made public at present, as some of the patents are not yet completed; but sufficient is known to give an approximately accurate description of the chief points of the construction. Mr. Sellon, the vice-chairman of the Anglo-American Brush Light Co., has for some time devoted his attention to secondary batteries, and since August last has taken out four or more patents, and has acquired others. M. Volckmar, whose name is associated with that of Mr. Sellon, has also taken out patents; and it is, we believe, on a combination of these that the new battery has been constructed. At any rate, Mr. Sellon found it necessary to purchase the patent acquired by Mr. Swan last year, which we described on p. 414 last volume. A reference to that description will show that the main idea of Mr. Swan's invention was to secure as large an amount of acting surface as possible in a small space, while preventing the spongy lead from falling in a heap at the bottom. He accomplishes that by corrugating the plates, or by making them cellular like a honeycomb cut vertically; and, according to Mr.

Sellon, that is practically the plan adopted with the new battery. The plates have no supports, and are in appearance solid pieces of metal kept apart by pieces of prepared wood, and immersed in the usual dilute solution of sulphuric acid. In reality, the plates are full of interstices or holes containing the material which is acted upon by the exciting liquid, and the changes in the chemical condition of which afford the means of storing energy in a form that can be subsequently given out as electricity. Taking the actual words of Mr. Sellon, we learn that this material, which is for the time a secret preparation, but which, we may safely assume, is an oxide of lead, minium, litharge, lead dross, or finely divided lead in some form or other, forms, so to speak, a solid alloy with the plates themselves, though in what degree it can be a solid alloy and yet be changed and rechanged by the taking in and giving out of a current of electricity is not quite clear. Probably all that is meant is that the oxidisable material is in one with the lead electrode, and does not require the supporting wrapper of asbestos, felt, or canvas, which, from its perishable nature, is the weak point of the Faure battery as publicly described. This absence of supporting material for the spongy coat of lead appears to be the chief improvement, if improvement it be, of the Sellon form of secondary battery, and the patentee looks forward to the time when electrodes weighing half a ton or a ton each will be used, a number being arranged in strong masonry tanks forming the reservoir which is to be the counterpart of the present gasometers. M. Faure writes that in December, 1880, he had a French patent in which perforated plates formed the principal claim, and since August last he has instructed the manufacturers that all plates without exception ought to be perforated. Further in February, 1881, he obtained a patent in which the use of gauze or cloth made with lead or other wire is especially mentioned as a substitute for felt as the support for the lead material on the electrodes. How far the various patents are valid remains to be seen, but it is clear that a great deal will turn upon the actual wording of the claims, for both De Meritens and Tommasi have brought out secondary batteries which are practically formed of perforated plates—see pp. 356, 536, last volume—and it would at least appear to be doubtful whether "perforation," in its various modifications, can be claimed as an invention. Be that as it may, however, the published statements concerning the new battery claim that within a box of a capacity less than half a cubic foot, 62lb. of active metal is confined, which yields, when properly charged, an amount of current equal to one horse-power per hour, giving off from 360 to 400 ampères at any required rate up to 40 ampères per hour. That is the small size; the large standard size contains nearly 300lb. of metallic composition, and can yield five horse-power of electrical energy for an hour, or from 1,800 to 2,000 ampères at any rate up to 250 ampères per hour. As described, the battery is simple, consisting merely of plates of alloy (presumably one in which lead forms the chief component) about a ¼in. thick, perforated with as many holes about ½in. in diameter as it is possible to make. The holes are filled with the metallic composition or preparation, and the plates are connected alternately, or in series, with thick copper wires. The weight of a large standard size cell complete is about 380lb., and of that it is asserted that nearly 300lb. consists of the active material by which the energy is stored. Apart from other considerations, which are probably sufficient in themselves to determine the use of lead for storage batteries, the low cost of that metal places it at a considerable advantage over others, and whatever may be the final result of the controversy between rival inventors, it seems clear that the secondary batteries which are to play an important part in the future of electric lighting will be made of lead on the principle long ago utilised by M. Planté—unless, indeed, which scarcely seems likely, someone invents a battery the working cost of which is nothing, by reason of the products of the chemical action being of a greater commercial value than the substances employed in forming the cell. Regarding the existing storage batteries as being practically equal so far as cost and maintenance are concerned, it is obvious that the superiority of one over the other will be determined solely by the percentage of energy returned, and from a careful series of experiments, the report of which has been presented to the Paris Academy of Sciences, we know that a Faure accumulator properly charged yields about 60 per cent. of the energy of the current put into it, but it is just possible that a larger return may be obtained by modifications in the method of charging. It follows, therefore, that if the new battery can give a better return, it must be an improvement, and as a trial is, we believe, about to be made by some representative experts, their report will be awaited with considerable interest.

THE MANUFACTURE OF INCANDESCENT LAMPS.

We have from time to time described the processes adopted in the preparation of the various parts of incandescent lamps, and have also given some idea of the difficulties which rival inventors have more or less successfully overcome. Mr. Crookes, in the specification of a patent lately issued, gives an interesting résumé of the different processes through which a completed lamp has gone, with the special devices forming the subject of his invention. The specification is No. 3799, of 1881, and contains eight figures, showing the lamps in various stages. The actual shape of the glass envelope is not of much importance, but we will assume that it has to be made from a piece of tube, which may conveniently be of the full diameter of the intended lamp. One end of this tube is, then, drawn down to a small diameter in such a manner that when the operations are completed and it is removed, that end will be rounded off. The other end is closed, and being softened for an inch or so, is blown out to form an extension of a smaller diameter than the main piece. While still soft, with a two-pronged tool, this extension is doubled inwards, the two points of the tool making little pits at the bottom of the doubling, which may be said to resemble the finger of a glove, drawn in upon itself for half its length. At this stage the extension may be separated from the main tube, but, whatever plan is followed, the two little pits are perforated, and conducting-wires sealed into them directly if platinum is the metal, or with the aid of arsenic glass or white enamel, when other metal is employed. In that case the wires are coated with the enamel or special preparation, and incased in little cylinders of glass, which are readily united to the glass that may now be said to form the stem of the lamp. If the extension has been already cut from the body of the tube, we have the latter as the envelope, and the former as the stem, which can be finished in any suitable manner for connecting to the brackets or supports. If the wires are of platinum they may be imbedded in the glass without liability to speedy fracture from difference of expansion; but there is a serious objection to the use of that metal in the fact that its specific conductivity is only about 18, taking silver as 100. Copper, which is much cheaper, and has a conductivity only slightly less than that of silver, cannot be used with safety, on account of the difficulty of making a good and permanent connection with the glass, but that is avoided by Mr. Crookes by means of a compound wire, having a core of copper or silver with a sheathing of platinum. The carbon filaments, or bridges, are now attached to the wire terminals by any of the usual methods; but in order to increase their rigidity, Mr. Crookes makes them of flat section, and gives a twist of a quarter of a circle in placing them between the terminals. Several bridges and stems having been prepared, the carbons undergo the most important operation of all. They are placed in a glass vessel suspended from glass-covered wires passing through a stopper or plate of vulcanised fibre, which is so placed at the top of the jar as to afford facilities for closing the vessel air-tight by a mercury seal. At the bottom of the vessel is a little cup containing chloroform, or in its absence a tube is provided for passing that liquid into the jar. Other substances may be used, as is well understood, the object being to render the carbon filaments homogeneous. The apparatus being arranged, and the air exhausted, the resistance of each bridge is measured, and if it is found to be too high, a current is sent through, raising the filament to a glowing state, until sufficient carbon has been deposited to increase the conductivity to the required standard. Bridges thus prepared are ready for the final operation: they are placed in the envelope, and the stem and neck are securely joined by fusion; the lamp is then exhausted and sealed in the usual manner. We gave a description of the method of preparing carbon filaments patented by Mr. Crookes on p. 247 of the last volume.

PRACTICAL NOTES ON PLUMBING.—XXXII.*

By P. J. Davies, H.M.A.S.P., &c.

Door-Action Water-Closets (Fig. 180).

There are a great variety of methods for fitting door-action closets; but in point of fact, though many plumbers make a great fuss when fixing them, there is very little more to be studied than in fixing a seat-action closet, and it will be readily seen that either may be fitted to the other. Fig. 180 illustrates a very simple method of connecting the door A to the crank B, which crank is in its turn connected to the cottage-valve D; this valve may be fixed as shown, or under the closet-seat at L, or in almost any other position. It will be seen that, if the door is pulled open from the outside, that the wire M will pull the crank B, and work the valve D, and as long as the door is kept open will the water continue to flow, unless the valve is of the waste-preventing description. Of course the valve can be fitted with a regulator or other retarding mechanism at P to keep it open for any given time (see K, Fig. 188).

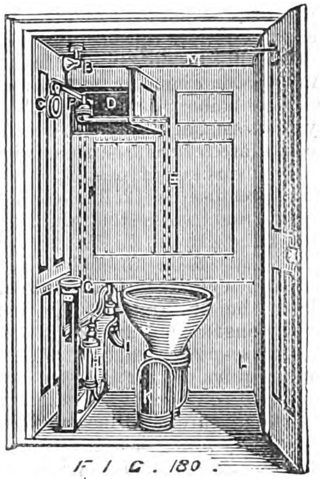

FIG. 180.

I cannot say that I am much in favour of door-action closets, although fitted in a sanitary point of view, seat-action being the preferable, and therefore when executing contracts of the door-action kind, endeavour to fix an additional pull-up valve as at G, H, I, which allows the user of the closet to flush the pan of the closet during the time it is in use; or if the extra pull is too much expense, I fix a pull to work the door-valve, as shown at K (Figs. 173 and 181).

Fig. 181 is a diagram of a door-action closet with the door opening inside. This arrangement is effected by fixing a pulley-wheel on the top part of the door-frame or lintel of the door, and with a chain connecting the door to the lever of the valve Q, as shown. This valve is also provided with an extra pull as at S, and an additional valve at C D, or the valves may be actuated by the use of a treadle or pedal as at A.

---

* From the *Building News*. All rights reserved.

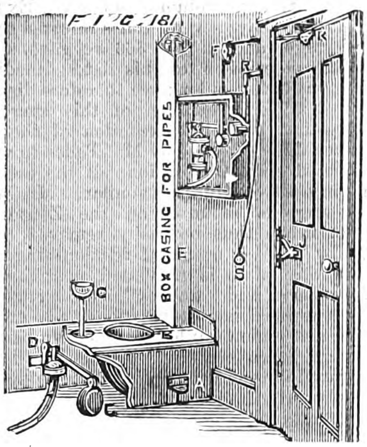

FIG. 181.

Fig. 182 illustrates another door-action closet, the door of which may be made to open either inwardly or outwardly, by fixing the cranked pull B as shown at Q, to point inwardly to the closet, and at right angles with the door: this however may be varied to suit circumstances. This valve may also be worked with a slotted pull-up pull H, I, or by treadle arrangement on opening the door, or otherwise.

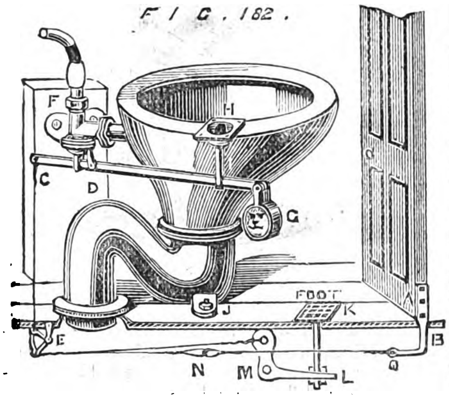

FIG. 182.
